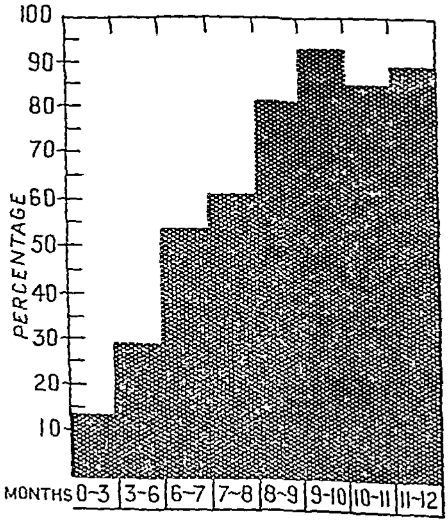
This disease attracts especial attention nowadays because there are signs of a threatening increase in several capitals. such as Paris, Budapest, and Berlin. Since 1926 the number of cases in Berlin has doubled. Far more alarming, however, is the malignant character suddenly taken by this disease. Whereas the percentage of diphtheria mortality in my hospital used to be 4–7 per cent., since 1926 the mortality has risen to 25–35 per cent. Even patients injected with large doses of serum on the first day have succumbed within 24 hours. In order to answer the question whether this means the beginning of a new pandemic we must glance at the epidemiological history of diphtheria. Since 1894 a decrease has been noticed all over the world. As diphtheria serum was discovered in 1894, the decrease of mortality has been attributed chiefly to this factor. This, however, cannot be the only one, because the morbidity also shows a striking decrease which cannot be influenced by the serum. Some writers explain the decrease of diphtheria morbidity by modern prophylactic measures, but a comparison of the decrease of diphtheria with the decrease of other infectious diseases casts doubt on this explanation. In the period 1866–1896 the decrease of scarlet fever in England was more marked than that of diphtheria, notwithstanding the fact we did not know anything about the virus of the former, and had not therefore the means of organising prophylaxis. It seems necessary to emphasise the fact that the decrease of diphtheria is not entirely due to therapeutic or prophylactic measures, so that the outbreak of a new epidemic is always possible. The fluctuations of the epidemic spread may depend upon the virulence of the bacillus and the susceptibility of the population. During the present epidemic in Berlin Dr. H. Schmidt, of Marburg, proved the virulence of bacilli cultivated from severe cases. After an injection of 0·05 c.cm. of a broth culture of living diphtheria bacilli guinea-pigs died within 24–36 hours.

Nevertheless, I doubt whether the fluctuations of virulence of diphtheria bacilli are responsible for the coming and going of the diphtheria epidemics. It seems very difficult to explain the striking and orderly course of diphtheria by the fluctuation of virulence alone. Diphtheria has a typical time-curve, as Gottstein has pointed out, with a constant ebb and flow. It appears as an epidemic extending over some 30 years, disappears for decades, and then begins another period of 30 years.

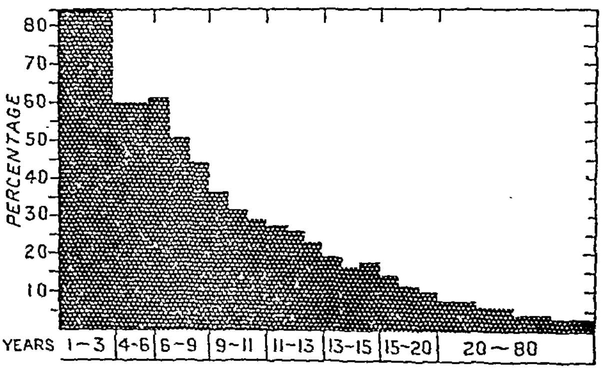
FIG. 2.



Percentage of positive Schick tests in first year of life.

The susceptibility of a population depends first upon inborn resistance, and secondly upon an immunity acquired by manifest or latent epidemisation. Experimental and epidemiological observations prove that there are inborn differences in resistance to diphtheria. Hirtzfeld has stated that the antitoxic titre, one of the most important factors of diphtheria resistance, represents an inborn quality, hereditary like the blood group. Gottstein, in his epidemiological studies, expresses the opinion that the natal predisposition of generations to diphtheria is subject to orderly fluctuations. In the epidemic course of diphtheria the most susceptible individuals succumb to the plague, and the surviving individuals have a high inborn resistance. The immune generation transmits this power to its descendants, and thus a series of non-susceptible generations comes into the world after a severe epidemic, and represent an unfavourable soil for the development of the microbes. In the course of decades susceptible generations arise from the crossing with individuals who had been spared by the epidemic, and under these conditions diphtheria can make its reappearance. There is no doubt that Gottstein's theory explains in a plausible way the orderly coming and going of epidemics. The facts must, however, be more complicated. One predominating factor of the highest importance for the susceptibility of the population has not been considered by Gottstein, and that is latent epidemisation. It stands to reason that latent epidemisation increases with an increase of diphtheria cases; that the spread of the disease is followed by an increasing immunisation of the population, which finally stops the epidemic. With the disappearance of diphtheria cases latent epidemisation also disappears, and generations susceptible to diphtheria gradually reappear. Latent epidemisation produces the same effect as selection by disease.

FIG. 3.



Percentage of positive Schick tests at various ages.

We can recognise, therefore, three factors which may explain the coming and going of epidemic diphtheria: (1) fluctuations of the virulence of Löffler's bacilli; (2) fluctuations of the natural resistance, depending upon selection; (3) fluctuations of immunity gained by latent epidemisation (latent immunisation).

What share these three factors have in the genesis of diphtheria epidemics is a very interesting problem of epidemiology which has been but little studied.

The Extent of Latent Epidemisation in Diphtheria.

We have three different ways of estimating this: (1) the immunity proof (Schick test); (2) the estimation of the spread of diphtheria bacilli by bacteriological methods; (3) epidemiological statistics.

TABLE III.

Mth.	Per cent.	Yr.	Per cent.	Yr.	Per cent.	Yr.	Per cent.
0–3	15	1–3	83·2	10–11	29·3	16–20	14·2
3–6	30	4–6	58·6	11–12	28·2	20–30	12·2
6–7	56			12–13	26·6	30–40	10·6
7–8	63	5–6	60·3	13–14	23·1	40–50	7·8
8–9	83·8	6–7	50·4	14–15	19·7	50–60	6·4
9–10	93·1	7–8	43·5	15–16	17·8	60–70	4·9
10–11	87·0	8–9	36·6	16–17	18·4	70–80	4·9
11–12	91·1	9–10	32·2				

Mth. = months. Yr. = years.

The Schick test has been carried out on millions of children in America, England, Holland, and Russia, and the theoretical elements of the reaction are, therefore, generally known. After an intradermal injection of one-fiftieth of a lethal dose of diphtheria toxin, as tested on guinea-pigs, all persons possessing no diphtheria antitoxin in their serum show a local inflammation, whereas those people who have more than one-thirtieth of an antitoxin unit in their serum show no reaction. Parker and Zingher showed that the positive result of the Schick test depends first of all on the age. (See Table III. and Figs. 2 and 3.)

The number of new-born Schick-positive individuals is small. It attains the maximum at the end of the first year of life, and then sinks rapidly and progressively. The negative test in the new-born infant depends on the transmission of antitoxin from mother to infant by way of the placenta, and perhaps with the milk. The extensive studies of Zingher showed that the gradual disappearance of positive Schick tests with increasing age is due to a latent epidemisation, and stands in a certain relationship to the density of the population. Zingher found that 87·3 per cent. of the school-children in the poorer, thickly populated districts, and 50·2 per cent. of those from the well-to-do classes were negative. The number of Schick-negative pupils in country districts is not more than 23·1 per cent. The greater the possibilities of contact, the higher is the rate of Schick-negative individuals.

The studies of Joannon and Lereboullet in Roumania are of great interest. These authors observed that all children showing a positive test on reception in a surgical department became negative after one year's stay at the hospital. The same result was obtained by Zingher. Among the children of a home he found that 33·3 per cent. of those who had been less than three months in the home were Schick-positive; of the older inhabitants not more than 3·4 per cent. These observations leave no doubt that the disappearance of positive Schick tests, corresponding to increasing age, is due to a latent epidemisation of the population by the diphtheria bacilli. A latent epidemisation of this extent cannot be accounted for by the number of diphtheria cases. I have calculated that, as far as Berlin is concerned, some 3·3 per cent. of the 10-year age-group have overcome diphtheria, but not less than 70·7 per cent. of this group show a negative Schick test. In other words, 67·4 per cent. of the population lose their susceptibility towards the diphtheria toxins at the early age of 10 in the way of temporary carriership.

Bacteriological Results.

The results of the Schick test show a degree of latent epidemisation that proves the diphtheria bacillus to be ubiquitous. This ubiquity, however, although accepted by Roux has been rejected in Germany by Robert Koch and his adherents. The answer to this question depends upon another problem, whether the pseudo-diphtheria bacillus, a very common saprophyte, and the diphtheria bacillus are identical or two very different species. No compromise has yet been reached between unitarians and dualists. I prefer to restrict myself in my epidemiological discussions to microbes which are generally recognised to be pathogenic—that is to say, to the virulent diphtheria bacillus.

We are well informed about the percentage of virulent diphtheria carriers in schools and barracks. The rate obtained depends on whether or not diphtheria cases have occurred in these institutions. In schools the average rate of carriers amounts to 10–20 per cent., but can be much higher. Seligmann, for instance, found that in a class where eight cases of diphtheria had been suspected, 33 out of 46 children were carriers. It is of much greater importance from an epidemiological point of view to know the number of diphtheria carriers in a dense population where cases of diphtheria have not occurred.

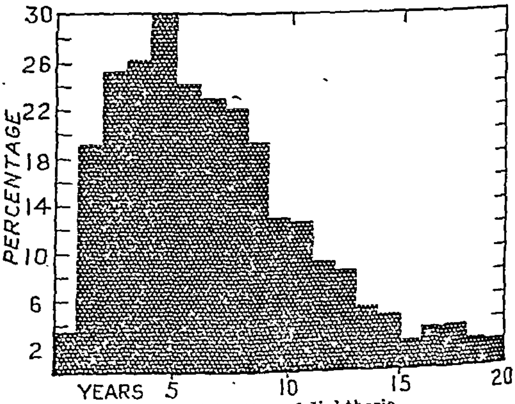
The very large number of investigations carried out in schools all over the world give a maximum of 5 per cent. and a minimum of 0·8 per cent. We can, therefore, consider that the average number of virulent carriers amounts to 2·5 per cent. Positive results are much more frequent if we analyse the nasal secretion of babies. Out of 55 babies Kirstein found 27 per cent. to be carriers of virulent diphtheria bacilli. If they were investigated daily from the first day of life, the rate rose to 85 per cent. Similar figures have been reported by Wiltschke. If we confine ourselves to the rates obtained for school-children and adults they will appear at first sight to be low. These rates seem to confirm those authors who deny the ubiquity of the diphtheria bacillus, but they are the results of one single investigation. We obtain quite different figures if we ask how many of the children will become carriers in the course of a year. It is known that diphtheria bacilli do not live long in a healthy organism, and if we suppose that on the average each school child carries diphtheria bacilli for four weeks in a year, we are allowing an ample margin. In order to maintain the quota of 2·5 per cent. of carriers we must multiply this figure by the number of months in the year, which gives the proportion of carriers among school-children as 30 per cent. If we apply these results to the entire population, we come to the conclusion that in one year about one-third of the population is infected with diphtheria bacilli without contracting the disease. This assumes latent epidemisation, which is practically equivalent to the ubiquity of the diphtheria bacillus.

TABLE IV.—*Giving the Age-distribution of Diphtheria.*

Age in years.	Per cent.	Age in years.	Per cent.	Age in years.	Per cent.
0–1	3·8	7–8	22·7	14–15	4·8
1–2	18·4	8–9	19·2	15–16	2·6
2–3	25·9	9–10	12·4	16–17	3·0
3–4	26·3	10–11	12·3	17–18	3·4
4–5	30·3	11–12	9·4	18–19	2·4
5–6	24·9	12–13	8·5	19–20	2·2
6–7	23·3	13–14	5·5		

Diphtheria is a children's disease (Fig. 4), but the correspondence of Table IV. with the curve of positive Schick tests (see Figs. 2 and 3) proves that the immunity of the older age-groups is not physiological but acquired by latent immunisation. The ubiquitous spread of diphtheria makes it impossible to state whether there would be a lack of adult immunity in a population which had been spared by the disease. Degkwitz asserts that the share of adults in the morbidity of diphtheria is higher in the country than in cities.

FIG. 4.



Age-distribution of diphtheria.

In Berlin the age-groups above 15 show a diphtheria morbidity of 17·1 per cent., whereas in the country town of Greifswald and its rural surroundings the morbidity of these groups amounts to 33·3 per cent. Statements regarding the influence of density of population and social conditions are very contradictory. The general opinion inclines to the belief that the spread of diphtheria is favoured by density of population, which increases the possibilities of contact. The observations of Reiche in Hamburg are very valuable. The conditions there are favourable, because the parts of the town inhabited by well-to-do people are isolated from those of the poorest classes. In the period from 1901–1914 the mortality was: rich, 5·9 per cent.; poor, 16·6 per cent. The morbidity-rate, however, was in inverse ratio: rich, 118·4 per cent.; poor, 86·9 per cent.

We should not, however, consider these rates as an expression of the real case-incidence, because in well-to-do families the physician is consulted for lighter cases.

If contact be the predominating factor it is obvious that the frequency of illness should be less in the well-to-do quarters than in thickly populated areas where the hygienic conditions are unfavourable. The local distribution of cholera among the rich and the poor in 1892 is an example of an illness where contact is of predominating importance, but where latent epidemisation has no great effect. The following figures give the number of cholera cases arranged according to the income-tax classes:—

Income.	Total cases.	Deaths.
600–1200 Mk.	116·84 per mille	59·69 per mille
More than 5000 Mk.	24·63 „	13·08 „

The relations between density of population and diphtheria morbidity find an adequate explanation only if we accept the theory of latent epidemisation.

Practical Conclusions for Prophylaxis.

Our sanitary precautions are based upon the belief that we are able to find the carriers by bacteriological tests and make them harmless. In special cases, such as the family, schools, and military barracks, these measures are possible and even necessary, but it is quite uncertain whether we should be able to achieve any results worth mentioning in an epidemic, seeing that in one year 30 per cent. of the population are temporary carriers. We lack information as to the immediate danger represented by healthy carriers. We have every reason to believe that a carrier is generally much less infectious than a patient. Doull and Hilario Lara determined the proportion between the cases infected by carriers and by diphtheria patients respectively, and found them to be as one to nine or ten. Contrary to the general opinion, they found no difference between the carriers of virulent and non-virulent diphtheria bacilli. They came to the conclusion that the danger of infection by carriers is negligible compared with the danger of infection by patients.

This conclusion may be admitted for single cases, but the small infective danger of carriers is more than balanced by the comparatively enormous number. During 1905 there were 2327 cases of diphtheria in Berlin amongst a population of 2,100,000. We may suppose that in the course of the year some 30 per cent., or 700,000 of the population, were carriers; since the carrier is 10 times less infectious than the patient, we will reduce the number to 70,000. This means that the patients suffering from diphtheria caused only 3·2 per cent. and the carriers 96·8 per cent. of diphtheria cases. The conclusions drawn are of such importance for public health measures that we must be very cautious and prove them by further experience. Similar figures are given by other epidemiological observations. We can obtain an approximate measure for the number of case-to-case infections if we state how many of a given number of diphtheria cases are produced by contact in the family. The League of Nations made inquiries among different nations, and the material is represented in Table V.

TABLE V.

Author.	Total of cases.	Percentage of contacts.
Moldovan (Roumania)	6,341	1·9
Hachta (Prague)	12,126	1·61
Intrario (Italy)	19,004	2·48
Jötta (Holland)	5,130	6·55
Chodzko (Poland)	—	2·5
Sweden	—	3·3
Bulgaria	—	2·15
Norway	—	17·6

Excluding Norway, the family contacts amount to an average of 2·9 per cent. Since contagion is nowhere so easy as in the family, we see that the number of case-to-case infections does not amount to more than 2·9 per cent. of the total of diphtheria cases, almost the same as the 3·2 per cent., calculated as caused by patients. If 97 per cent. of all diphtheria cases are infected by carriers, it is hopeless to fight against a diphtheria epidemic by finding out carriers and isolating them. In epidemics a higher rate takes place in the family contacts. Gottstein's observations on diphtheria in 1895, the climax of an epidemic, showed that the number of family contacts amounted then to 17·6 per cent. of the total of all diphtheria cases.

Active Immunisation.

It is clear why, in spite of the most intensive sanitary precautions, the decrease of diphtheria has been less than that of other diseases, the agents of which have up till now not even been discovered. The classical methods of Koch's prophylaxis, which have proved of use in infectious diseases of the digestive tract, seem to be of no value in diseases transmitted by droplet infection. The fight against diphtheria epidemics is only possible by active immunisation. The methods used in England and America are well known.

More than 1,000,000 children have been immunised against diphtheria, and the material should be sufficient to give an estimate of the value of the method, if we take into consideration the Schick test alone. It seems possible to change a positive Schick test into a negative one in 80–90 per cent. both with toxin-antitoxin mixtures and the anatoxin of Ramon. We are entitled to suppose that these children are, with few exceptions, also immune to diphtheria. But what about the 10–20 per cent. of children who cannot be immunised successfully? Is not this inability to produce antitoxins after immunisation the expression of a special lack of resistance to the natural diphtheria infection? If this is so is not the total of diphtheria cases exclusively recruited from this group of bad antitoxin formers? The number of diphtheria cases is extremely low in proportion to the total of the population; it varied in Germany during 30 years between 0·1–0·6 per cent. The group of bad antitoxin formers is therefore sufficient to provide all the diphtheria cases. This is not a mere hypothesis, for Reich and Weiss have stated that of diphtheria convalescents not more than 50 per cent. become Schick negative. It is reasonable to suppose that the diphtheria patient falls ill because he is unable to form antitoxins. Should this supposition prove correct we cannot rely on the Schick test. The children who are actively immunised are the ones who would become negative in any case through contact with the bacilli, without contracting the illness, and the number of really susceptible individuals is, therefore, not reduced.

The value of immunisation as a preventive measure against diphtheria can only be seen by comparing morbidity statistics among immunised and non-immunised children without considering the Schick test. Unfortunately, although the number of inoculated children is high, the statistics at our disposal are very poor. The only extensive statistics have been made by Park, and refer to 90,000 Schick-tested children. Of these 56,000 were originally negative; 33,000 who had given a positive reaction were actively immunised. In the first group there occurred five cases of diphtheria, in the second group nine cases. Hence, even after artificial immunisation the degree of immunity is lower than in natural immunisation by latent infection. To estimate the value of active immunisation Park controlled these results by a second group of 90,000 children, neither tested nor immunised, in which there occurred 56 cases of diphtheria. In comparing these numbers we must assume that the second group also contained 56,000 Schick-negative children with five cases of diphtheria. Therefore, comparing 33,000 non-immunised Schick-positive children with 51 cases and the same number of immunised originally positive children with nine cases, we find that the number of cases among the non-immunised is five and a half times as great as among the immunised. The American statistics show, therefore, the practical value of active immunisation. Similar statistics should be published in countries where immunisation is commonly in use, and especially in those where diphtheria is widespread and dangerous.

SCARLET FEVER.

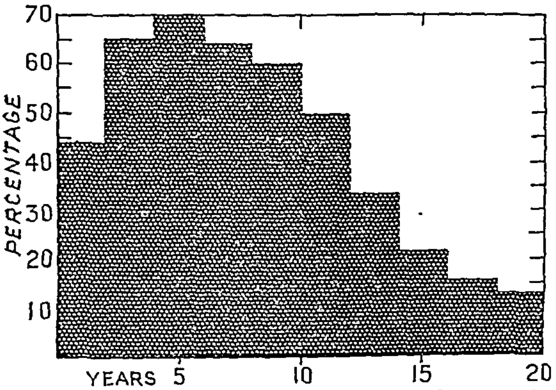
That the epidemiology of scarlet fever also depends upon the extent of latent epidemisation can be seen from the results of the Dick test. Table VI., compiled by Zingher, shows that the result of this test depends, like that of the Schick test, upon age. (See also Fig. 5.)

TABLE VI.

	Positive per cent.		Positive per cent.
0–6 months	44·8	5–10 years	33·2
6–12 ,, ...	65·3	10–15 ,, ...	22·8
1–2 years	71·6	15–20 ,, ...	16·8
2–3 ,, ...	64·2	More than 20 years	14·4
3–4 ,, ...	60·5		
4–5 ,, ...	48·2		

The Dick test becomes negative earlier in the city than in the country, and among the poor than among the well-to-do. At the beginning of this century Moser and Gabritschewsky regarded the streptococcus as the microbe of scarlatina, and built up the prophylactic and therapeutic methods which are now in use. But their evidence was not conclusive, and the streptococcal ætiology was generally rejected, until Dochez and the Dicks established it, and refuted all objections. There were two arguments against the streptococcus: (1) the impossibility of differentiating the scarlatinal streptococcus from other streptococci; (2) the almost complete immunity after scarlatina, in contrast with the lack of immunity following other diseases caused by streptococci.

FIG. 5.



Percentage result of positive Dick tests at yearly age-periods from 0–20.

Dochez, Avery, and Lancefield claim to have differentiated the scarlatinal streptococci by means of agglutination; I have not been able to confirm these results and others have been equally unsuccessful. Some technical difficulties have not yet been elucidated. The Dick method of differentiating the scarlatinal streptococci seems to me to be of great importance. The Dicks could demonstrate a toxin specific for scarlatinal streptococci and absent in all other streptococci. All animals examined have proved insusceptible to this toxin, and only the goat shows an inconstant local inflammation after intradermal injection. Man, however, is very susceptible and shows all the characteristic symptoms after injection. After an intramuscular injection of about 0·5 c.cm. of a culture filtrate of scarlatinal streptococci, a person susceptible to scarlatina shows, after only a few hours, the following signs: vomiting, high fever lasting for 48 hours, and accompanied by a typical scarlet exanthem, scarlet tongue, and eosinophilia. This disease differs from genuine scarlatina only in that it is not contagious, because it is not an infectious but a toxic disease. The scarlatina toxins are demonstrable with the Dick test, which consists of the intradermal injection of 1/1000 c.cm. of a culture filtrate. Its specificity is not yet quite clear. Most streptococci reach to a larger quantity of filtrate (ca. 1/100 c.cm.), but the specificity of the Dick test is based on the following facts:—

1. It is only positive for persons susceptible to scarlatina; convalescents from scarlatina and individuals who have already had it give, with few exceptions, a negative result.

2. The scarlatina toxins can be neutralised with serum of scarlatina convalescents as well as with an artificial antitoxic scarlatina serum.

Results contradicting the specificity of the Dick test seem to be explicable by the use of filtrates containing also proteins of the bacteria, which give allergic reactions opposed to the specific Dick test. That is to say, they cause positive reactions in just those who are sensitised because they have recovered from scarlatinal infection. In order to eliminate the fallacy due to the presence of proteins it is always necessary to control the test by a toxin solution previously heated to 100° C. for one hour. In my experience even this control is not sufficient, probably because there are also thermolabile proteins in the filtrates. Another argument raised against the specificity of the Dick test is that sometimes streptococci cultured from other diseases form a specific scarlatina toxin. I have never met with such a strain, and according to the recent investigations of Jacobson and Szirmay they are rare. I cannot regard their existence as an objection to the specificity of scarlatinal streptococci, which differ from others only by the formation of a specific toxin, but possess the pyogenic properties of all streptococci. It is therefore easy to understand how a scarlatinal streptococcus may produce a suppuration or a puerperal sepsis in an individual immune to scarlatina. There are other equally convincing facts in favour of the ætiological rôle of streptococci. The two Dicks, as well as Nicolle, Conseille and Durand, were able to obtain typical scarlatina in susceptible persons by painting the throat with a small quantity of scarlatinal streptococci. Finally, Dochez and the two Dicks succeeded, by immunising a horse with the toxins of scarlatinal streptococci, in obtaining an antitoxic serum of excellent therapeutic effect in scarlet fever. I have used this serum in 300 cases, and in uncomplicated scarlatina its efficacy is quite marvellous. A further proof of the specificity of this serum is that it exhibits the so-called Schultz-Charlton blanching phenomenon; in other words, it is capable of setting free the toxins of scarlatina in vivo, bound until then to the cells of the blood capillaries. In my opinion the ætiological rôle of the *Streptococcus hæmolyticus scarlatinæ* is better established than that of any other pathogenic agent. In Germany it is still regarded as very doubtful and it has been pointed out that a filtrable virus might also play a part. I consider this supposition entirely hypothetical and superfluous. We have filtered the water which had been used for gargling by persons suffering from acute scarlet fever; we painted the throat of susceptible persons with the filtrate and found that even convalescents from angina caused by hæmolytic streptococci remained free from scarlatinal symptoms.

The Contagiousness of Scarlet Fever.

In collaboration with my assistant Dr. Deicher I undertook the task of analysing bacteriologically the path of scarlatina contagion. The streptococci were identified by the Dick test. We found that the skin scales previously purified did not contain any streptococci; we may therefore conclude that they do not eliminate the scarlatinal microbe. We did not find any streptococci in the urine. The principal focus is the tonsil where we, like Dochez, found them in all cases. Besides that they were only found in the pus. The transmission occurs principally by droplet infection, and infection through objects in common use must be considered. In the beds, on the walls, and in the air of rooms occupied by scarlatina patients we found numerous streptococci.

The occurrence of streptococci can be used to recognise scarlatina patients and healthy microbe carriers. The practical application of such an investigation, however, involves many difficulties. The differentiation of streptococci by agglutination seems to be uncertain, and the toxin proof is much too complicated to be applied as a routine. I am inclined to deny that the occurrence of hæmolytic streptococci in the throat has in itself diagnostic value. Although the streptococcus hæmolyticus does not normally belong to the bacterial flora of the human throat, we meet with it in other diseases which we must exclude in diagnosing scarlatina—e.g., common angina. The occurrence of hæmolytic streptococci is therefore of no diagnostic value in acute scarlet fever; on the other hand, the absence of hæmolytic streptococci in the throat makes scarlatina improbable. This may be of practical value. If a patient has just recovered from scarlet fever we cannot be quite sure that the hæmolytic streptococci in his throat are scarlatinal, but we can conclude that a convalescent in whose throat we do not find any streptococci is completely free of scarlatinal microbes. Although there is no absolute safety, there is at least the same probability as in the bacteriological control of diphtheria. We have no information as to the period of contagiousness of scarlatina convalescents. It is customary in Germany to restrict the isolation to six weeks, or until desquamation ceases. We do not know whether many convalescents are free of microbes before this, but we know for certain that even after six weeks' isolation transmission has occurred in the family. We have found hæmolytic streptococci in the throats of 100 per cent. of convalescents on the day of their leaving the hospital after six weeks. This easily explains the frequency of return cases. We concluded that the patients failed to lose the microbes because they were constantly being reinfected. We therefore organised an intermediate "ventilation" block (Lüftungsstation), to which the patients who had but few microbes in their throats were transferred. No recent scarlatina cases were admitted to this block. The consequence was that the majority of patients could be dismissed after a six weeks' stay, free from streptococci. Many of them lost the streptococci after three to five weeks. On one occasion, however, a patient suffering from a wound scarlatina was admitted to the hospital; she had as usual in such cases no hæmolytic streptococci in the throat. She was therefore transferred to the intermediate block, and remained for three weeks free from streptococci. After that time recent cases of scarlatina were admitted to this block because the scarlatina wards were overcrowded. Two days afterwards we found hæmolytic streptococci in the throat of this patient.

We have made a practice of dismissing patients from the intermediate block irrespective of the period of illness and the existence of desquamation if the throat has proved free of hæmolytic streptococci at three examinations. Many patients could be dismissed after three to five weeks. Among 39 patients dismissed without bacteriological examination there were four return cases. Among 50 patients dismissed after examination no return cases occurred. A bacteriological control is therefore a far greater guarantee against return cases than routine dismissal after six weeks and after disappearance of the scales. Bacteriological control will also save the patient from unnecessary restrictions and reduce public expenditure. Of 40 private patients more than half had no streptococci after a period of two to three weeks.

Before the American investigations were known in Germany Degkwitz had used scarlatina convalescents' serum in the prophylaxis of 1000 cases with excellent results. I have obtained the same good results, and have never seen a failure among hospital cases treated with serum taken six weeks after the outbreak of the disease. Its efficacy is due in the first place to the antitoxin content, and sera of poor efficacy can be excluded by the Schultz-Charlton phenomenon. We proved by this method that the serum of many adults contains almost the same quantity of antitoxin as convalescents' serum. This fact is of eminent practical importance when sufficient convalescent serum is unobtainable. Convalescents' serum has a considerable bacteriological power against scarlatinal streptococci, a power which is lacking in artificial immune serum. This may have a share in its prophylactic effect. We use 5 c.cm. of convalescents' serum for children and 10 c.cm. for adults. The protection may last about four weeks. If no convalescents' serum is at our disposal we use artificial immune serum, but its prophylactic efficiency seems less reliable and disappears two weeks after injection. In order to avoid unnecessary serum injections, the individuals needing protection may be selected by the Dick test. This previous testing is useful in children's homes where enormous quantities of serum would otherwise be needed. In a children's home in Berlin in which cases of scarlet fever had occurred 126 inmates were tested by Dr. Deicher; 43 had a positive reaction, 83 a negative one. Of the 43 positive children 7 took scarlet fever, of the 83 negative children only 2 fell ill with scarlet fever, and 3 with angina. Thus a higher percentage of the positive children caught scarlet fever (18 per cent.: 2·4 per cent.). An absolute protection is therefore not guaranteed by the negative Dick test. Bacteriological control and serum prophylaxis place at our disposal preventive measures which are very effective in single cases but, as in diphtheria, these methods are only of limited value in public health campaigns against scarlatina, on account of the enormous number of healthy microbe carriers. Only active immunisation would ensure complete success. In 1912 Gabrischewsky in Russia immunised by means of vaccines of scarlatinal streptococci. The results seem to have been very good, and it is surprising that these methods fell into oblivion. Since the discovery of the scarlatina toxin immunisation by its means has been resumed on a large scale in America, Hungary, and Poland. There is at present no agreement with regard to the dosage. The skin test dose is generally accepted as the toxin unit, but the amount used for immunisation differs widely. The total number of children inoculated with scarlatina toxin all over the world may already amount to 100,000. The results agree in showing that the experimenters have succeeded in changing a formerly positive Dick test into a negative one in 50–80 per cent. of the cases. It will need a longer period of observation to determine whether a protection against natural infection is also attained by this immunisation.

THE TREATMENT OF RHEUMATIC CARDITIS.*

By GEOFFREY BOURNE, M.D. Lond.,
SENIOR PHYSICIAN, EAST LONDON HOSPITAL FOR CHILDREN, SHADWELL; CHIEF ASSISTANT TO THE CARDIOGRAPHIC DEPARTMENT, AND CASUALTY PHYSICIAN, ST. BARTHOLOMEW'S HOSPITAL.

THE treatment of rheumatic heart disease is doubly discouraging; long-continued efforts so frequently appear to have been wasted, and the patients themselves are often the brightest and most cheerful of those in a children's ward. There is a very real danger, therefore, of feeling that whatever is done the outcome is likely to be the same, and of allowing one's efforts to relax. Only by holding to first principles and by refusing to be disconcerted by the long list of failures are the best results likely to be obtained.

In the treatment of active infective disease there are two objects: the removal of the causative agent and the amelioration of symptoms. Seeing that the cause of acute rheumatism is as yet unknown, although streptococci are suspect as accessory, if not as primary agents, attention is of necessity directed to the second of these aims. The primary object of treatment will be made most clear by considering two main factors which interact throughout the duration of the disease. They are (1) the continuous

---

[*] A post-graduate lecture given at the East London Hospital for Children, Shadwell.

nature of the infection, and (2) the situation of the lesion. Infection in acute rheumatism is a continuous process. Occasionally the disease seems to run a clear and well-defined course, but more often it is insidious in its onset and treacherous in its simulation of quiescence. During this period of activity, which may last for many months, the virus is continually at hand and ready to take advantage of the slightest opportunity. Evidence of this is found in the continued fever, the leucocytosis, and the periodic outcropping of nodules. The other factor is the situation of the lesion. The valvular lesions occur almost invariably along the line of apposition of the cusps. The pericardial lesion, by its very definition, is found where the visceral and parietal layers rub. The articular lesions are similarly situated at points open always to mild trauma. The nodules occur where the elbows, ankles, and knees are most exposed to knocks or pressure, and where the occiput and spine meet the pillow and mattress. Nor is it unreasonable to imagine by analogy that the lesions present in the substance of the myocardium are similarly affected by stress and pressure, though in this case the exact physical determinants are less easily analysed. The myocardial disease is, of course, the ultimate factor in prognosis, but that of the valves is more easily visualised, and is more readily used as an example.

Continued mild trauma and continued infection thus seem likely exciting causes of those permanent lesions, the cumulative effect of which gives acute rheumatism its chief fatality. From this it follows that, if the infection cannot be suppressed, attention should be continually directed to reducing trauma. Rest during the period of active disease is imperative. A reduction in the pulse-rate of 10 beats per minute means that the inflamed cusps are snapped together 14,400 times less in the 24 hours, and a reduction in the pulse-rate from 130 to 80 saves them from 72,000 collisions in the same period. The cumulative saving of 10 beats per minute for three months cannot be over-estimated. Expressed in percentages, a saving of 10 beats per minute, the rate falling from 90 to 80, means a reduction in the total number of beats occurring in 24 hours by nearly 9 per cent., and a saving of 50 beats per minute, the rate falling from 130 to 80, means a reduction in the 24-hourly number by 26 per cent. These figures also apply to the saving in the stress and pressure which probably involve the equally important myocardial lesions during systole.

The diminution in rate has other interdependent results: diastole is prolonged, the total time spent in systole is shortened, and the cardiac work is reduced to a minimum. During diastole the heart muscle-fibres receive their nutritive coronary blood-supply and eliminate waste products; thus a shortened diastole, or a faster rate, encroaches upon the time available for this. If we apply these principles to treatment the canon that emerges is that *the heart-rate must be kept as low as possible during activity.*

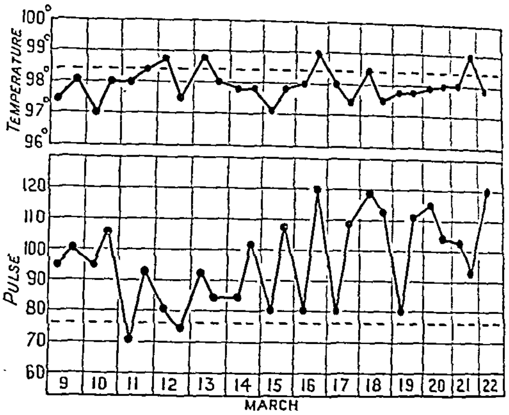
The Assessment of Activity.

The activity of rheumatic carditis is assessed by attention to the following points: Presence of nodules; presence of fever; presence and type of tachycardia; cardiac dilatation; presence of a leucocytosis; variation in the hæmoglobin percentage; appearance of the patient; and electrocardiograph tracing.

Nodules.—The appearance of rheumatic nodules is to be taken as indicating that active rheumatic carditis is present, their presence that an active rheumatic carditis is either present or very recent. Their significance is not altered in the absence of fever. Nodules are more easily seen than felt, especially when small. The elbow, for example, should be held flexed in a good oblique light and the skin made to slide over the deeper tissues; the nodules are often seen to move slightly under the sliding skin. In doubtful cases the two sides should be compared.

Disappearance of nodules does not necessarily mean that the disease has become quiescent, though it usually suggests an abatement. (See Fig. 1.)

FIG. 1.



The chart of a child suffering from active rheumatic carditis. Both temperature and pulse curves prove the presence of activity. The irregular variation in the former, although a higher reading than 99° is not reached, is significant.

Fever.—The temperature chart in active rheumatic carditis has two characteristics; pyrexia is usually present in spite of adequate salicylate administration, and the temperature curve shows unusual changes in level. Fever is significant, even when the readings reach such unsensational figures as 98·8° or 99°. The changes in level are most readily appreciated from the chart, and frequently occur in an apyrexial patient. Absence of fever does not necessarily indicate that the disease is quiescent. Nodules may appear in an apyrexial patient. The phrases "bed fever" and "constipation fever" are sops to conscience.

Tachycardia.—The spikiness of the pulse chart during activity is even more striking than is the irregularity of the temperature curve. To appreciate it, it is necessary to chart the pulse-rate properly. The practice of writing a double line of figures at the bottom of a chart is merely a means of hiding valuable evidence. In most cases of active carditis the pulse-rate varies very greatly within a few days, producing a curve like a silhouette of some mountain range. With quiescence the undulations become milder and ultimately vanish.

Cardiac Dilatation.—The relative position of the apex beat from time to time, as measured in inches from the mid-line, is of considerable value in estimating activity. A dilating heart in acute rheumatism is inevitably a poisoned heart, and one diminishing in size is as frequently one whose freedom from toxæmia allows tone to be re-acquired. Should the position of the apex beat remain unchanged, no conclusion one way or the other can be drawn. Two sources of fallacy must be borne in mind. An adherent pericardium may fix the apex beat, and a full meal may, in a child, displace it to the left by as much as half an inch. All measurements are, of course, taken with the patient lying flat on the back.

Leucocytosis is an almost constant finding in active acute rheumatism.[1] It is seldom very high, figures near 12,000 being usual, except with the onset of an acute pericarditis, when considerably higher values occur. The persistence of even a mild leucocytosis is strong evidence that the disease is still active; its absence is unusual, but does not necessarily indicate that infection has ceased. The persistence of a leucocytosis in the absence of any other sign or symptom of activity suggests recrudescence.

Hæmoglobin Percentage.—Nearly all cases of active rheumatism have some degree of chlorotic anæmia. Weekly estimation of the hæmoglobin percentage is a valuable, accurate, and easy means of obtaining evidence upon the progress of the case.

---

[1] Swift, H. F., Miller, C. P., and Boots, R. H.: Jour. Clin. Investig., 1924–25, i., 197.

Appearance of Patient.—There is no doubt that the facial expression and appearance of a patient in whom the disease has become inactive is often characteristic. There is an absence of puffiness and of the fevered, slightly emotional expressions that flit across the face of the rheumatic child. The appearance suggests calm, relaxation, and comfort.

Electrocardiograph Tracing.—A mild degree of heart-block is not uncommon in the active stages of acute rheumatism. It is manifested by a prolongation of the P–R interval to 0·2 seconds or more. If present and frequently measurable, it will be an additional check upon the prognosis of a still active lesion. Its absence is of no help in assessing the presence or degree of activity.

Relation of Signs of Activity to Treatment.

If one or more of the above signs of activity be present in a patient recently diagnosed as suffering from active rheumatic carditis, they should be carefully followed until one and all have disappeared. Persistence of any of them indicates that the patient should be confined to bed. The time of final disappearance of the last sign should be noted, and ideally the patient should lie flat in bed, with one thin pillow, for at least another two months. At the end of this period further steps may be taken at intervals of a week. These are, in order, an allowance of extra pillows, sitting up for half an hour, for an hour, and so by gradations of half an hour up to three hours. During this time massage of the legs should be instituted. Finally the patient is allowed to walk. First a few steps to a chair only are taken, and by degrees more and more exercise is allowed. If facilities exist and the climate permits, these stages of treatment can with advantage be undergone in the open air.

Steady progress in convalescence is only possible in patients who show none of the signs of activity. Should any one sign reappear, the patient should go back to bed and recommence the unabridged programme.

Prevention of Tachycardia.

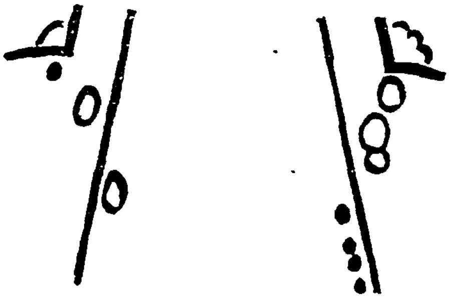
Rest in bed, with one flat pillow, is the only way of keeping the pulse frequency at its lowest figure. The known causes of physiological tachycardia (exercise and emotion) must, of course, be avoided. There is no drug upon which reliance can be placed to produce a bradycardia. Digitalis[2] will occasionally do this, even with a normal cardiac mechanism, but the effect is infrequent and sometimes transitory.

The Tonsils.

One of the known facts in the pathology of acute rheumatic carditis is the close relation it bears to tonsillar disease. This is so generally accepted that there is no need for further elaboration here. The value of tonsillectomy as a preventive is, however, still under dispute. The practice at the East London Hospital for Children is to remove the tonsil when there is evidence of tonsillar disease, provided the rheumatism is sufficiently inactive. The measure is not devoid of danger, and great care is necessary in estimating the risk of lighting up a fresh spell of infection. The guiding principle is the degree of active carditis, as deduced by the criteria already described. Considerable experience is necessary and each case must be judged individually. The points to be considered in determining whether or not tonsillar disease is present are (1) the history of sore throats, (2) an associated lymphadenitis, (3) the appearance of the tonsils.

A history of sore throats is significant when they have been frequent, or where a rheumatic attack definitely began with them. Any enlargement of lymphatic glands in the neck is to be carefully watched for, and it is wise to examine the neck from behind. Three areas are specifically palpated: just beneath the angle of the jaw, between this and the anterior border of the sternomastoid in the upper third of the neck, and behind the posterior border of the muscle in the lower half of the neck. Any abnormalities are charted, and their variation watched from day to day. In this way it is often possible to decide whether there is an active tonsillar lesion or not. Infections of the scalp, teeth, and middle ear must, of course, be excluded. Changes in the size of the lymphatic glands are charted in the manner shown in the diagram. The two short-angled lines indicate the angles of the jaws, the two oblique lines indicate the sternomastoids. The line enclosed in the jaw angle represents the tonsil, and the lymphatic glands are also shown. Sizes and consistency can be indicated, a black spot marking a hard and a circle a soft gland. An individual soon invents his own formulæ for size and hardness. The exact condition can then be charted in a few seconds with a minimum number of strokes. (Fig. 2.) The size and appearance of the tonsils are valuable criteria if abnormalities are present, but disease may exist even though the tonsils are not enlarged and look superficially healthy. Points indicating disease are enlargement, redness, raggedness of surface, and pus in the crypts. Tonsils should be considered diseased if the history is characteristic or if there is evidence of glandular enlargement.

FIG. 2.



Left Side.—The left tonsil is smooth and slightly enlarged. Below the angle of the left jaw is a small hard gland, lower and between it and the sterno-mastoid is a larger soft gland; lower still and posterior to the muscle is another similar gland.
Right Side.—The tonsil is large and its surface is irregular. Beneath the angle of the jaw is a large soft gland, and between it and the sterno-mastoid two similar glands adherent to one another; lower and posterior to the muscle is a string of hard, shotty glands.

The outstanding danger of tonsillectomy in a rheumatic child is the possibility of lighting up a dormant acute rheumatism. If a state of sufficient quiescence has not been reached, the operation may be followed immediately by fever, tachycardia, cardiac dilatation, and the appearance of a fresh crop of nodules. I have seen three cases of acute rheumatic pericarditis arising in this way; the harm done far outweighs any theoretical benefit. If, however, a state of sufficient quiescence has been attained, and if adequate salicylate dosage is given before and after tonsillectomy, such troubles can be avoided. The dose should be grs. 15–20, with double the quantity of sodium bicarbonate, two-hourly by day, and four-hourly by night if the patient is not asleep. A potassium permanganate gargle is freely used.

Other Measures.

Sodium salicylate is the only drug known to have an effect upon acute articular rheumatism. Evidence has been adduced to prove both that it has and that it has not an effect in the cardiac type of the disease. In my experience it certainly does no harm. It seems to lessen to some extent the number of recrudescences in children attending as out-patients, and on the whole it is valuable in the treatment of the active cardiac infection. The doses given to in-patients are grs. 10–20 two-hourly, with twice the amount of sodium bicarbonate.

Gargles are invariably given, and most children quickly learn the art of using them. Potassium permanganate is probably the best; it is easy to carry in the form of crystals, and these are dissolved by the patient or the mother in warm water until a light red colour is obtained.

---

[2] Sutherland, G. A.: Quart. Jour. Med., 1918, xii., 183.

These two forms of treatment have proved their value. Others which have here been given an extended clinical trial in acute and subacute cases during the last eight years are: vaccines, protein shock, the intravenous disinfectants (flavine, gentian-violet, and neokharsivan), and artificial sunlight.

A series of patients were treated with sensitised and desensitised vaccines, with the collaboration of Dr. Mervyn Gordon on behalf of the Medical Research Council. The vaccines were prepared from streptococci derived from post-mortem material of cases of the disease. No encouraging results were obtained.

Protein shock was only tried in four cases, doses of 25–100 million typhoid bacilli being given intravenously. Since each case showed more signs of activity afterwards, no further investigations were made.

Intravenous flavine was given to 12 chosen patients and intravenous gentian-violet to another 12; neither form of treatment had any effect. Intravenous neokharsivan is now under trial.

Artificial sunlight was given to six chosen cases; three were definitely worse and the others were unaffected.

INTRINSIC CANCER OF THE LARYNX.

THE OCCURRENCE OF IMPAIRED MOBILITY OF THE AFFECTED CORD AND ITS VALUE IN DIAGNOSIS AND PROGNOSIS.*

By Sir StClair Thomson, M.D. Lond.,
FELLOW OF KING'S COLLEGE; EMERITUS PROFESSOR OF LARYNGOLOGY IN KING'S COLLEGE HOSPITAL.

It is a truism that stereotyped errors or exaggerations in medicine are difficult of eradication. This is my excuse for returning to the subject of impaired mobility in intrinsic cancer of the larynx.[1] The present observations are based on 70 cases operated on through a laryngo-fissure.

Historical Survey.

The occurrence of this valuable symptom appears to have been first noted by Lublinski[2] and Semon[3] about the same date. In 1886 Semon unfortunately committed himself to the statement that a malignant tumour causes "a considerable impairment of the affected cord at a very early period, and is one of the most valuable and constant points of differential diagnosis." Twenty-one years later, as the result of further experience, Semon saw the need of modifying this opinion considerably[4] but, unfortunately, it had then become embedded in the text-books, and it was difficult to diminish the exaggeration which the weight of his authority had established. His earlier and somewhat misleading opinion is still widely held, so that cases are often dismissed as "quite innocent," or are not referred to an expert in time to secure a lasting cure with a useful voice (by the laryngo-fissure route of operation), simply because "the cord moves quite freely."

I propose to show that interference with the movement of a vocal cord affected with cancer is an occasional symptom, and one of much value, but that it is not an early nor a frequent one.

Author's Material.

My conclusions are based on cases (*a*) operated on by laryngo-fissure, (*b*) with the diagnosis verified in every instance by the microscope, and in which (*c*) the after-history of each case has been followed up to the present date, or until the patient's death. They cover a period of 28 years. Cases which were only seen in consultation, or not operated on, or operated on by other routes, have been left out of consideration. I have had 70 such cases. Mere mechanical interference with the excursions of the affected cord, due to the projection of the growth, was noted when it was present, but is not here included as an instance of impaired, intrinsic mobility.

In these 70 cases the affected cord was quite mobile in 39. In 21 cases the mobility was more or less impaired, being described as "flagging," "sluggish," "limited in movement in anterior (the usually affected) half," or "hardly any movement." In 10 cases there was no movement at all in the affected cord, and it was described as "quite fixed." Thus, in 39 cases, more than half the total, this symptom of impaired mobility was entirely absent.

In five cases paresis developed while under observation. In some it was noticed a month after the first inspection; in others at varying intervals, even up to nine months. (This last case was successfully operated on and survived ten years to die of tubercle.) Where the diagnosis is doubtful, particularly where a biopsy is decided against and a case is being kept under observation, it should be carefully scrutinised once a month to detect any onset of this symptom.

Deductions.

Any defect of movement in a vocal cord, due to cancer, is caused by the neoplasm penetrating into the subadjacent intrinsic muscles. The more a growth projects above the surface, the less likely is this to happen. It is in such cases that a biopsy is often both practicable and, diagnostically, satisfactory. When the neoplasm is imbedded in a cord it tends to penetrate deeply and it is more difficult to obtain a satisfactory portion for section. It is in such cases that the occurrence of impaired mobility is a valuable symptom.

As regards Prognosis.—The occurrence of paresis in a cord, due to an infiltrating carcinoma, is of unfavourable prognosis. In my 39 laryngo-fissures on a mobile cord, two must be left out of account, as they were only operated on this year. In the remaining 37 cases no less than 31 were free from disease at the end of three years (=84 per cent.). Of the cases with impaired movement 15 out of 20 passed the three-year limit without recurrence (75 per cent.). In 10 cases, in which the cord was quite fixed, one died from other causes within 18 months. Of the remaining 9 cases, with complete fixation of the cord, only 4 were free from recurrence three years afterwards (=44 per cent.). Of these cases, 3 died from other causes five, seven, and ten years later. One is still alive and well 11 years afterwards.

As regards Treatment.—Free mobility of a vocal cord affected with carcinoma would indicate the suitability of operation by the laryngo-fissure route, particularly if the disease has not extended to either extremity of the cord and the subglottic area is free. Under the same conditions, a simple paresis or impairment of movement does not contra-indicate the same operation. The removal should be as wide as is possible and the larynx should be carefully and regularly scrutinised once a month during the subsequent year, as any recurrence can be successfully dealt with by a partial or complete laryngectomy.

When the cord is quite fixed, and the disease does not invade either extremity, the same plan of treatment can be successful. Even when, under the same condition, the subglottic space is invaded, a lasting cure may, with the same method, be secured. But if, with a fixed cord, the disease has extended to the base of the arytenoid posteriorly, or crossed the anterior commissure, or extended to the ventricular band, or to the epiglottis, or (downwards) as far as the cricothyroid membrane—some more extensive operation is required.

[3] Heath's *Dictionary of Practical Surgery*, London, 1886, i., 895.

[4] Trans. Medical Society, London, 1907, xxx., 113.

Summary.

1. Impaired mobility of a vocal cord is not a necessary nor an early symptom of intrinsic cancer of the larynx.
2. It is met with in less than half (about 44 per cent.) of the cases presenting themselves as suitable for operation by laryngo-fissure.
3. It is more apt to develop in an embedded or infiltrating neoplasm than in a distinctly sessible or projecting growth.
4. When present it is a valuable symptom in helping to distinguish a malignant from an innocent neoplasm. It is of little value, and may even be misleading, in diagnosing a malignant growth from a tuberculous or syphilitic deposit.
5. Its absence is of good augury and hence the desirability of making an early diagnosis before it has developed. As regards prognosis, its presence is an unfavourable symptom.
6. Its absence or presence is a valuable factor—in conjunction with other data—in determining the most suitable treatment.

THE ENLARGED PROSTATE AND ITS NON-OPERATIVE TREATMENT.*

BY F. HOWARD HUMPHRIS, M.D. BRUX., F.R.C.P. EDIN., D.M.R.E. CAMB.

FEW diseases from which men of middle or advanced age suffer have so tried the skill of the physician and the endurance of the patient alike as enlargement of the prostate gland. It has been estimated that one in every three men over 60 complains of symptoms caused by an enlarged prostate, and to these sufferers must be added others in whom the enlargement "gives rise to no appreciable symptoms." An enlarged prostate causes local troubles connected with urination, and also, owing to its reciprocal relation with the cerebro-spinal centres, to neurasthenic symptoms. Indeed, Dr. Snow stated that the prostate should usually be examined in men suffering from neurasthenia. Mental sluggishness often accompanies enlargement, and sometimes the only symptom of a chronic prostatitis may be inactivity of the mind. The symptoms for which the patient seeks medical advice arise from the mechanical obstacle to the urinary flow. He often has to strain before the flow can be established, and when the act is apparently finished some more urine dribbles away, often a few minutes after the patient thought his bladder was empty. The time occupied in passing water gradually becomes longer. Nocturnal urination and frequency of micturition are common. When a patient has these symptoms, apart from his discomfort, he is not free from danger. The bladder has lost some of its tone and it is usually distended, so that attacks of cystitis are not uncommon. The patient is liable to attacks of complete retention of urine or to septic poisoning. In the great majority of cases he is instructed in the art of passing a catheter, and his catheter life begins; it would be a bold man who characterises this as either free from risk or a pleasant prospect.

Drug and Gland Treatment.

Drugs are of little use except to relieve the symptoms of irritation, to improve the condition of the urine, or to combat complications, such as hæmorrhage. Cases have been reported of an enlarged prostate, one an ordinary senile enlargement and another a traumatic inflammation in a young adult, in which the administration of ergot (liq. ext. ergotæ, ʒj.) four-hourly, and later, night and morning, apparently reduced the size of the prostate. Organotherapy in this country has not been used to the extent which theoretically it deserves; in France it has been almost a routine treatment for nearly ten years. The argument for the use of prostate extract was based on a theory which may be roughly outlined as follows:—

The fact that prostatic hypertrophy quite commonly follows the functional retirement of the testes has caused many observers to believe that there is some relationship between the endocrine activities of both these glands. It is believed that when the testes become functionally inactive the prostate becomes enlarged in a compensatory fashion, just as other ductless glands enlarge when closely related glands are put out of commission. It is generally accepted that, when deep-seated infective processes and essential new growths of the prostate gland can be excluded, there remains a form of enlargement of the prostate gland which is closely related to waning gonad function. This should theoretically respond to treatment by organotherapy, which would supplement the endocrine function of the testes and thereby lessen the probable necessity for over-activity on the part of the prostate. The extract is administered in capsules, grs. 1½ of the dried extract, and in ampoules containing the equivalent of this dose in a physiological salt solution.

Surgery has without doubt saved many lives and relieved this condition, with operations such as prostatectomy and castration. A masterly epitome of the relation of surgery to this disorder may be found in the Bradshaw lecture given before the Royal College of Surgeons of England by Sir Cuthbert Wallace.[1]

Electrical Treatment.

Electricity will usually give rapid relief (Roger), and in some cases complete relief, from all symptoms. The use of electricity is comparatively little known, since it is mentioned but rarely, and then only in terms of disparagement, a typical sentence reading: "So far it must be conceded that electricity, radiotherapy . . . yield very incomplete, fugitive results."—(Dr. G. Marion, Paris.) I have had experience of electro-therapeutic measures in the treatment of enlarged prostate for over 25 years, and have found, and am finding, them daily of the greatest service.

The three forms of treatment which I am about to describe are: (1) the static wave current; (2) X rays; and (3) diathermy.

Histologically, the enlargement is a proliferation of the constituent elements of the prostate, but in all forms of prostatitis the consistence is less firm and the texture somewhat more open and spongy. There is more fluid than natural in the gland tissue; the mucous membrane may be thinner and more vascular and the duct orifices larger. This mechanical obstruction requires a mechanical means to remove it, and nothing can compare with the static wave current, which was accidentally discovered by Dr. W. Benham Snow some 30 years ago when he was treating an intrapelvic neuritis. The patient had a large, tender prostate, which was found to be softened and reduced in size after the application of the electricity, and Dr. Snow says that no work he has done since has given him greater satisfaction. In 1902 Dr. Snow gave me the benefit of his experience, and since then I have used his method continuously, and can recommend it with confidence. The very nature of the disease makes it peculiarly suitable to the action of the static wave current. We have a structure which is partly glandular and partly muscular. We can place an electrode alongside the diseased structure and apply the current almost directly to the pathological gland. Muscular contractions are induced, the gland tissue is contracted, and the products of inflammation are squeezed out. These accumulations having been mechanically expelled, a tonic circulation is restored to the gland by the electrically stimulated cell activity. Each successive treatment gives more and more power to the muscle-fibres and more tone to the glandular structure, leaving the gland smaller and of more normal consistence until there is little left but healthy muscle-fibre and healthy gland tissue, except in those very long-standing cases where the hyperplastic fibrous tissue still persists.

---

* Paper read at the Second International Congress of Radiology at Stockholm, July 30th–August 1st, 1928.

[1] Brit. Med. Jour., Nov. 19th, 1927.

The treatment discovered by Snow remains practically the same to-day. The details are as follows:—

> A metal electrode is passed into the rectum and pressed against the gland. It is attached to the positive side of the machine, the negative being grounded. The sliding rods, touching each other at first, are gently and slowly opened according to the toleration of the patient. The treatment continues for 20 minutes. The effect on the prostate tissue is strictly mechanical, and there is no electrolytic or thermic action. When the current is applied with a metal electrode in the rectum over the prostate gland it causes alternate recurrent contraction and relaxation of the tissues. The current is regulated in the rate of discharge at the spark gap by controlling the speed of the machine, so that the periods of contraction alternate with the periods of rest at the rate of 120 or so to a minute. The sinusoidal current from the morse wave generator—the wave water interrupter of Turrell and the de Wattville current, or the Smart-Bristow coil with hand interruptions—may be used when a static machine is not available, but no current can replace the static.

It occurred to me that sparking the prostate should have an especially good effect in obstinate cases, and therefore I had made an ordinary metal prostatic electrode on a vulcanite handle. Thus, on the principle of Snow's spark director, a spark applied to the knob would have the effect of a spark applied to the gland. In all sparking the spark gap should be wide open, the negative side of the machine connected to the platform by means of the shepherd's crook, and the positive side and the ball attached to separate groundings. I cannot say, however, that this gives any better results than the ordinary static wave current.

Patients often remark, even at the end of the first treatment, that the perineal sense of weight is less, and after daily treatment for a week or ten days and tri-weekly séances thereafter for a month or six weeks, the congestion and engorgement have disappeared, and with them the pain, discomfort, and necessity for getting up at night. The condition of the bladder has also improved, and I am inclined to attribute this, in part at least, to the stimulation of those unstriped muscle-fibres which continue to the bladder. These fibres have to be stimulated to contract, and with this exercise would naturally acquire more power and tone, not only in their prostatic portion but in their vesical part as well, and would thus give more muscular force to the bladder and greater power to get rid of urine.

Often after one treatment the gland is reduced in size, loses its tenderness, and is softened throughout its entire structure. The treatment should be given often enough to prevent a relapse—probably daily. As the gland grows smaller and softer the subjective symptoms grow less and less until they disappear entirely.

In the very aged, or where there is much fibroid tissue, we can only hope for an abatement of the inflammatory process, but even here we get a marked improvement in the tonicity of the unstriped muscle-fibre, both prostatic and vesical. In other cases, even where the condition has lasted for a number of years with cystitis and difficult micturition, we get an improvement so marked with the forcing out of the infiltrating exudates that in the patient's estimation it amounts to a cure.

Until seven or eight years ago, for cases where infection complicated the enlarged prostate, I used glass vacuum electrodes energised by the static machine and connected to the negative side of the machine, the positive being grounded. My theory was that a germ-destroying effect was produced.

Iodine and thiosonamin have been administered by ionisation, but the results have been disappointing. Both these methods were introduced by Neiswanger, who lays down the following rules:—

> A large sized prostatic gum-elastic catheter is used in which is a galvanised iron wire stylet; round this is loosely wrapped some cotton-wool soaked in a solution of thiosonamin. The end of the catheter is provided with numerous perforations. The instrument is attached to the positive pole, with the negative pole connected to a large abdominal pad. About 10 milliampères are allowed to flow for ten minutes every fourth day.

I have little practical experience of this method, and have found it inferior to other forms of treatment.

A Typical Case.

A man of 65 consulted me on Sept. 22nd, 1911. About six or seven years previously he had noticed frequency of micturition, especially at night. This had apparently got a little better, but lately it had troubled him acutely. He got up at least five times a night to pass water; he could retain urine for four hours at a time during the day, but it was more comfortable to pass it every two hours or so. He also complained bitterly of a second involuntary flow some minutes after finishing micturition, of discomfort before and after micturition, and of a dragging sensation during the day. He also had a pain in the back, which he called lumbago. Physical examination showed that an enlarged and fairly hard mass, the size of a hen's egg, occupied the whole of the prostate. There was nothing in his history or general health to call for comment, except that he had never had any venereal disease.

Treatment was instituted at once with the static wave current on the prostate, and after 20 applications was discontinued on Nov. 9th, the prostate being about half the size that it had been on Sept. 22nd. The records for these days were as follows:

Date, 1911.	Retired to bed.	Disturbed for micturition.	Date, 1911.	Retired to bed.	Disturbed for micturition.

* Discomfort after micturition less. "Lumbago" pain gone. Frequency of micturition the same.

The patient arose each morning at 7.30 and passed water. From the end of October he was disturbed but once nightly.

X Ray Treatment.

Much benefit has been obtained by the use of X rays, but cases must be carefully selected. The simple adenomas are extremely sensitive, but the presence of fibrous tissue reduces the sensitivity, so that adenofibromas and fibromyomas react in inverse proportion to the amount of fibrous tissue present. When the prostate is large and soft, good results can be expected, but X rays are of little value in the treatment of hard, bossed glands elevating the floor of the bladder. Suitable cases respond rapidly; the nocturnal frequency is diminished after only a few irradiations, and a reduction in the size of the gland can soon be appreciated. Cystitis is a contra-indication to X ray treatment, as a severe exacerbation is likely to follow the application of the rays.

Technique.

I use only one port of entry—the perineum. The treatment may be given with the patient lying on his side on a couch, but I have found it more convenient to use a special stool, like a high office stool, which can be placed over the X ray tube. In the seat is a circular aperture, 4½ inches in diameter, through which the rays are directed. When the patient is seated on the stool the perineum can be accurately centred and the cheeks of the buttocks easily separated and maintained in position. The testicles are protected by a layer of lead rubber fixed to the seat.

The best results are obtained with rays of moderate hardness in divided doses. I use an 8-inch equivalent spark gap with 2–3 mm. aluminium and ¼-inch boiler felt as filters. Six doses of 1/6 B. are given over a fortnight, and the treatment is repeated at the end of six weeks. Two or three series are usually sufficient, but I have many patients who come twice a year for a single course as a prophylactic against recurrence, even though they may not be worried at the time by frequency or other symptoms of enlargement.

Diathermy.

So far, only non-infective prostatitis has been considered. In cases of gonococcal prostatitis diathermy is the treatment to be adopted. Its value has been pointed out by E. P. Cumberbatch, whose experience and writings on the subject have been of the highest value. The rationale of the treatment depends upon the power of the diathermic current to destroy the bacilli *in situ*. The temperature which will kill the micro-organism is one which is harmless or even beneficial to the tissues.

For the modern technique we are also indebted to Dr. Cumberbatch. He has perfected electrodes containing a thermometer which registers the heat which exists, or has been produced, by the current at the junction of the instrument and the mucous membrane. The electrode is inserted in the rectum, so that the prostate gland rests upon the head of the electrode when the patient is lying on his back. The electrode is attached to one terminal of the diathermy machine and the other terminal is connected to the indifferent electrode, for which I use a metal pad placed on the abdomen. Cumberbatch uses a belt of sheet lead 3½ inches wide and 4 feet long. This "is placed around the pelvis and the overlapping ends are passed through a stout wire loop and bent back so that the belt holds firm and even contact with the skin." Whichever indifferent electrode be used, the current should be turned on and increased very slowly, a sensation of heat but not of pain should be produced; if the patient complains of pain the current should be reduced until he is absolutely comfortable. This will usually be at a temperature of 106° F. or slightly higher, though at the first treatment 104° or 105° F. should be the maximum. The treatment should be of 20 minutes' duration, and be repeated every other day.

With these three forms of treatment, and a sufficient intelligence on the part of the patient to obtain medical advice before it is too late, the different types and degrees of enlarged prostate will cease from troubling, and the middle-aged man will have his rest at night undisturbed.

ALEUKIA HÆMORRHAGICA: MYELOPHTHISIS.

WITH A REPORT OF A CASE.

BY W. J. S. REID, B.Sc., M.D. ABERD., M.R.C.P. LOND.,
HONORARY PHYSICIAN, ANCOATS HOSPITAL, MANCHESTER.

CASES showing a hæmorrhagic diathesis are extremely difficult to place in their proper groups, and although the diagnosis of purpura hæmorrhagica may be sufficient to label the case, I think attempts should be made to separate the groups. Frank[1] has described cases which he considers are worthy of a separate name and classification as aleukia hæmorrhagica, and this case seems to correspond with those he describes.

The patient was 20 years old, a plasterer.

Family History.—Father and mother alive and well. No history of any blood trouble. Two brothers alive—perfectly healthy, but pale and anæmic-looking. Mother is also pale, and sons "took after her" in appearance. No history of any illnesses.

Previous History.—Perfectly healthy. Never lost a day's work through illness, and was a particularly energetic and efficient worker in his father's employ.

Present Illness.—Eighteen days before consulting his doctor he felt a little out of sorts, languid and vaguely tired. He noticed a few spots, like small blood vesicles, under the skin, but continued his work for a fortnight. At the end of this time the spots had faded, but a few more appeared and his urine contained blood. His doctor sent him to bed. There was a small subconjunctival hæmorrhage and some oozing from the fauces. He had a small superficial cut on the left middle finger which had not healed as quickly as usual, but he and his father were positive that the spots preceded this by 10 or 12 days, during which he continued work. When I saw him, in consultation with Dr. G. Ferguson, of Oldham, he was pale and coughing up blood. Blood was oozing from the fauces, which showed much swelling and gangrenous-looking clot. The cut on the finger was covered by gangrenous clot. The blood had reappeared in the urine. He was given calcium lactate and two injections of normal horse serum of 20 c.cm. each, which failed to control the hæmorrhage. He was admitted to hospital next morning, when he was extremely pale and practically moribund. Blood was still oozing from the fauces and anterior nares and from the lower lip.

Blood Examination.—Red cells 1,200,000 per c.mm. No nucleated cells. Hæmoglobin index 0·8. Anisocytosis. No basophilic punctation. No polychromasia. White cells 1750 per c.mm. Polymorphonuclears about 9 per cent. Small lymphocytes 84 per cent. Large lymphocytes 4 per cent. Myelocytes and promyelocytes 3 per cent. Thrombocytes—platelets—very much reduced in number, under 1/6 normal. Coagulation time not examined. Blood type II. Widal and Wassermann reactions negative. No tubercle bacilli in sputum or growth on culturing the blood, but the throat swab showed many rod-shaped organisms; no diphtheria. Van den Bergh's reaction negative, direct and indirect.

300 c.mm. of whole blood from the father were transfused into the patient and improvement took place at once. Bleeding ceased almost immediately, and in a few days the finger healed up and the throat condition cleared almost completely. The submaxillary lymphatic glands on both sides, which were enlarged, diminished rapidly. No enlarged glands were found anywhere else in the body, and no enlargement of the spleen was elicited by percussion, nor was the spleen palpable. The liver was not enlarged. Hæmic murmurs were present, but there was no signs of any organic heart lesion. The urine contained a slight trace of albumin, but no blood.

Treatment.—Gargle of acid carbolic for throat condition. Novarsenobenzol painted on the sloughing area. An acid mixture containing dilute hydrochloric acid thrice daily. Calcium lactate thrice daily. Intravenous injections of N.A.B. 0·45 g. at four days' interval. Three injections in all were given and no obvious effect was seen. Epistaxis began four days after the transfusion and was controlled by plugging the nares. Three days later some hæmaturia also occurred, and, as the epistaxis still continued, a second transfusion of 200 c.mm. was given, the father again being the donor.

Daily examination of the blood during this period showed no nucleated red cells. Hæmoglobin index never exceeded 0·9, and the white cells averaged 1000 per c.mm. with the granular cells never above 9 per cent. Thrombocytic count never improved. On the day following the second transfusion the index was still 0·9. The total white count had risen to 1250 per c.mm., but the granular leucocytes still formed only 9 per cent. of the total. Next day the white cells fell to 1050 per c.mm., and the hæmoglobin index was 1.

Four days later the patient showed petechiæ of the upper eyelids and became restless and vomited. Lumbar puncture yielded normal fluid. The restlessness changed gradually to delirium; the eyes deviated to the right and then to the left and the pupils became inactive; breathing became stertorous with left facial weakness; left arm flaccid, but not completely paralysed; left leg completely flaccid and paralysed; tendon reflexes absent, with extensor plantar response. In right leg tendon reflexes increased and extensor plantar response was present. After three hours patient expired. During the stay in hospital the patient had a temperature varying from normal to 104° F. on one occasion, but the average daily swing was from 99° to 102°.

Post-mortem Examination.

Brain: Large petechial hæmorrhages were present over the vault of both hemispheres near the longitudinal sinus. Multiple hæmorrhages all through the cerebral substance. No blood in the ventricles. Cerebellum studded with minute hæmorrhages all over its surface and through its substance.

Thorax: No lung disease; some œdema of both bases. Pleural cavities contained a small amount of blood-stained fluid. Some petechiæ on pleural surfaces.

Heart: Pericardial sac contained about 10 oz. of blood-stained fluid. Two large ecchymoses were present under the endocardium. All the valves were healthy and there was no sign of any endocarditis.

Spleen: Weighed 5 oz.; appearance normal. Culture taken—no growth. Malpighian corpuscles were not unduly prominent. No iron reaction.

Liver: Weighed 3 lb. Slightly fatty in appearance; capsules peeled normally. No perihepatitis. No iron reaction. In microscopic section slight necrosis seen in the centre of the lobules.

Gall-bladder and ducts healthy. Bile normal.

Kidneys appeared healthy except for some petechiæ in the substance and under the capsule. Adrenals normal.

Stomach and bowels were normal. A large old hæmatoma was found in the right iliac region behind the ascending colon and peritoneum. Appendix and caput cæcum healthy.

Thyroid normal. Lymphatic glands not enlarged except under the angles of the jaws; substance dark-coloured from blood resorption. Mediastinal glands not enlarged.

Bone-marrow: No red marrow present in humerus (upper end) or femur (upper end) or in sternum; substance cream-coloured in appearance. Medulla under microscope showed a complete absence of normal red cells, and no nucleated red cells or megakaryocytes were seen. No phagocytosis observed. The predominant cells were lymphatic. Much fat was present.

Summary of Case.

The striking features of this case are: the comparatively sudden onset of the illness and the complete absence of previous history of blood disease, or, in fact, of serious disease of any kind; the acuteness of the condition once started; the profuse hæmorrhages into the tissues and especially from the fauces, and the continued raised swinging temperature. Diagnosis is impossible in such a case without careful blood examination, and this places the condition within the group of diseases labelled aplastic anæmia. The case, clinically, gives the impression of an acute infective condition, which it may have been, but certain factors are against this. No organism could be isolated from blood culture and none from the spleen post mortem. The rise in temperature was definitely a later phenomenon than the petechial hæmorrhages. The foul condition of throat and lips, and of the small wound on the left middle finger, were at least a fortnight later than the petechiæ. The spleen was not enlarged and there was no enlargement of the lymph glands with the exception of the submaxillary glands, and this swelling was definitely a result of blood resorption and local infective material. Moreover, should an organism be isolated from the blood in such a case, it is by no means certain that it can be put down as the cause of the condition. Organisms are not uncommonly found before death, and in cases like that described, where the granular leucocytes are reduced to a minimum, organisms might exist in the blood as a result, and not necessarily as a cause of the agranulocytosis, which is really a breach of one of the body's defences.

Aplastic Anæmia.

"Aplastic anæmia," according to Hurst,[2]

> "is the name given to a rare condition in which the bone-marrow cells cease to produce blood corpuscles in sufficient quantity to compensate for their destruction. In very rare cases it appears to be a primary condition. More frequently it is secondary to a primary hæmolytic anæmia in which the over-activity, which is the normal response to both hæmolytic and hæmorrhagic anæmia, leads to exhaustion; possibly the toxæmia, which is the cause of the excessive hæmolysis, also damages the bone-marrow. Primary aplastic anæmia is characterised by the absence of nucleated red cells or other evidence of activity of the bone-marrow in response to the anæmia."

In this description the author may have had chiefly in mind the red-cell-forming function of the bone-marrow, but when all the functions are taken into consideration the definition is very sound. The division of primary from secondary aplastic anæmia is evident, but further subdivision is necessary to distinguish the cases which compose the groups, as they exhibit very diverse clinical pictures. The function of the bone-marrow in health is the production of cells of various kinds, and the circulating blood may be regarded roughly as the mirror of its efficiency. The cells produced normally by the bone-marrow are the erythrocytes, the granular leucocytes of various kinds, and the thrombocytes, the so-called platelets. The work of Wright, to which very wide, if not universal, recognition has been accorded, showed that the thrombocytes are the product of the megakaryocytic cells of the bone-marrow. The old ideas that they were artefacts, or extruded or separated particles of the other cells of the blood, are untenable. The function of bone-marrow may be regulated by a hormone, as is tentatively advanced by Hurst. Where the hormone over-stimulates, the result is one of several conditions—e.g., polycythæmia rubra, or myeloid leukæmia; where the hormone is deficient we get aplastic anæmia. The theory is attractive in its simplicity and helpful, but it is merely a hypothesis, and hardly explains the selectivity of the hormone in its control over the production of the various cells. The truth is that the bone-marrow can be impaired or stimulated in some, or all, of its functions.

Frank,[1] in 1915, described a disease-picture, in which all the cell-forming functions of the marrow were reduced very gravely, and there was a profuse hæmorrhage. This he regarded as a separate disease, and gave it the name aleukia hæmorrhagica or myelophthisis. Schulz and Friedemann,[3] in 1922, described a condition which was also an aplastic anæmia with reduction of the granular cells in the blood with, however, glandular and splenic enlargement, but without the hæmorrhagic tendencies of the other. They named the condition agranulocytosis. Koehler [4] has fully described three cases of the aplastic anæmia type, two of which showed severe lack of all the marrow-formed elements of blood. Erythropenia, leucopenia, with relative lymphocytosis, and thrombopenia were present, and a prominent clinical feature was hæmorrhage from the mouth and fauces. In the third case the erythrocytes and thrombocytes were not reduced much from normal, and no hæmorrhages occurred. All three had raised temperatures and gave the impression of infection; no organisms were found, however, to explain the condition. Ellmer [5] has reported a case which agrees with the picture of aleukia hæmorrhagica as given by Frank and by Koehler, and with the picture of the case here reported. Schulz and Friedemann insist on the absence of thrombopenia and hæmorrhages in their description of the condition which they term agranulocytosis. This is most probably not a disease sui generis, but a stage of a disease, probably an infection leading to partial exhaustion of the functions of the marrow, of which the granular leucocytic-forming function seems to bear the brunt.

In the case now reported all the cell-forming functions have been disastrously affected, the only cells which exist in the blood in anything approaching normal condition and quantity being the lymphocytes, and they do not have their origin in the bone-marrow. The essence of the aleukia hæmorrhagica (which descriptive name may be used till ætiology is better known) is that all the functions of the bone-marrow are severely affected and hæmorrhage takes place from the fauces, which seems to be a site of election, but the hæmorrhages may be general. A raised temperature always accompanies the condition. It is a disease of unknown causation, and naturally can only be diagnosed after a very careful examination of the history of each case. Morawitz,[6] for instance, has reported a case of aplastic anæmia following typhoid fever, and Schilling [7] one case following sprue. One of the essential features of aleukia hæmorrhagica is the thrombopenia, which is associated with the hæmorrhages. This is quite in line with the modern conception that the thrombocytes are a great factor in influencing the coagulability of the blood. The faucial condition in the case under my care—of oozing and necrotic membrane formation—had, in my opinion, the same causation as the other hæmorrhages in the body, and was the result and not the cause of the blood condition.

Benzol stands out as the most frequent cause of injury of the bone-marrow, so much so that it has been introduced by Korányi in an attempt to reduce the number of granular cells in myeloid leukæmia, but given up because of the impossibility of controlling its effects. Radio-active thorium X has been used by von Plesch and Falta for the same purpose, and given up for the same reasons—unreliability of action and impossibility of control. Over-response to Rontgen rays had produced the condition of aleukia hæmorrhagica, as recorded by Decastello, Ross,[8] Frank, and Whitby and Jackson.[9]

Treatment.

This is at best palliative. In view of the destructive changes in the marrow it cannot be otherwise. Where the cause is known, its removal, as in the case of benzol and X rays, is followed by regeneration unless the condition has gone too far. Where, however, the ætiology is unknown—i.e., in the primary essential aleukia hæmorrhagica—nothing seems to be of any service. Transfusion, as in my case, may cause a tremendous improvement for a little time—it brings the patient back almost from the dead—but at best its effect is only temporary. Removal of the spleen has been recommended for primary pernicious anæmia by Hoff,[10] Decastello,[11] Klemperer, and Hirschfeld,[12] Walterhöfer and Schramm,[13] and of late has been practised in this country in hæmorrhagic conditions where platelets are reduced to a minimum. In aleukia hæmorrhagica the reasons for the extirpation of the spleen, which are valid in both the above conditions, are present and cogent, but after serious consideration—there being no manifest enlargement of the organ—I decided against the operation. With a case less acutely ill the proceeding might be tried.

Summary.

The case described showed the following features. (1) An illness of fairly acute onset with petechial hæmorrhages—later hæmorrhages from the fauces and from the kidney. Death was due to hæmorrhages into the brain. (2) Temperature of septic type but later in onset than petechiæ. (3) No signs of regeneration in spite of severe anæmia due to hæmorrhages. (4) Leucopenia was present, granular leucocytes were practically absent from the circulating blood, and small lymphocytes formed a very large proportion of the total white cells present. (5) Reduction of thrombocytes to a minimum. (6) Absence of splenic and lymph gland enlargement. (7) Bone-marrow, examined post mortem, showed absence of erythrocytes, erythroblastic cells, megakaryocytic cells, and granular cells.

The condition is a clearly defined clinical picture and should be considered as a separate entity—aleukia hæmorrhagica or myelophthisis—and, pending further investigation, forms a subclass of primary aplastic anæmia.

"PAY-BEDS" AT THE ROYAL NORTHERN HOSPITAL. An anonymous supporter of this hospital has promised to give £35,000 towards the erection of a wing for pay-beds on the lines suggested by the report of the King's Fund on condition that an equivalent sum is raised before the end of the year. The Royal Northern claims to have been the first of the great London hospitals to provide these facilities. The same donor has given £1500 for the purchase of radium and £700 for a new electric lift.

Clinical and Laboratory Notes.

CEREBRAL EMBOLISM

DUE TO AN UNUNITED FRACTURE OF THE CLAVICLE AND SUBCLAVIAN THROMBOSIS.

BY A. GURNEY YATES, M.D. EDIN., M.R.C.P. LOND.,
PHYSICIAN, SHEFFIELD ROYAL INFIRMARY;
AND
DENTON GUEST, M.B., CH.B., SHEFF.,
PATHOLOGIST, SHEFFIELD ROYAL INFIRMARY.

THE following case, though unquestionably rare, is of importance because it establishes beyond doubt the manner in which cerebral lesions are occasionally caused by bony abnormalities at the root of the neck, and in particular by cervical rib.

The patient was a woman of 41 who came to the out-patient department complaining of pain and weakness in the right hand and forearm, made worse by movement. It had lasted some months and was slowly getting worse. The hand was cold and bluish and no pulse could be felt anywhere in the limb. On examining the neck the right clavicle appeared to be fractured. She was unaware that she had fractured her clavicle, but she was an epileptic, though she had had no fit for several years. The Wassermann reaction was negative, and there was no evidence of any central nervous lesion. The radiogram showed quite clearly an ununited fracture of the right clavicle. It was suggested that the condition might be congenital, but if that had been the case the two fragments would have been in a line, which they obviously were not.

The case at once recalled that about two years ago at a clinical meeting of the Neurological Section of the Royal Society of Medicine, Dr. C. P. Symonds showed two cases of left hemiplegia associated with a cervical rib on the right side, and absence of any pulse in the right upper limb. The explanation suggested was that the pressure of the cervical rib on the subclavian artery had led to thrombosis, and that the thrombus had extended backwards to the point of junction of the right common carotid, and a portion of it, becoming detached, had formed an embolus in one of the branches of the left middle cerebral artery. If this explanation were the true one there was a risk of a similar occurrence in this case, and a surgical colleague was consulted as to whether any operation was advisable. Arrangements were made for the patient to come into hospital, but before anything could be done an embolus occurred. She was taken suddenly ill with pain in the head and throat, vomited, and said she could not see. She gradually became unconscious and incontinent. At first there was some weakness of the right lower face, but later this spread to the left side, which was blown out more than the right on expiration, and the left arm and leg became paralysed. Some movement still occurred in the limbs of the right side on stimulation. The plantar reflex on the left side was extensor, on the right flexor. The knee- and ankle-jerks were only just obtainable. The abdominal reflexes were absent. The coma became deeper, with paralysis of all four limbs, the temperature rose to 105° F., and she died seven days after the first onset.

Pathological Findings.

A full autopsy was performed upon this case in the usual manner and the findings recorded. For the sake of correlation with the clinical picture, we shall describe the pathological changes in the order in which we consider they arose.

Right Clavicle.—An old-standing ununited fracture at the junction of the middle and outer thirds was present, with fibrous union and the formation of a false joint. The free ends were quite smooth and were displaced backwards and slightly downwards towards the right subclavian artery.

The Systemic Circulation.—The arch of the aorta, innominate, and right subclavian arteries were carefully dissected out in situ, and upon opening these vessels an organised and very adherent thrombus was found, occupying the first and second parts of the subclavian. This thrombus commenced about ⅜ in. distal to the division of the innominate into the right common carotid and subclavian arteries, and extended along the latter for a distance of 1½ in. The third part of the subclavian appeared free from thrombosis, but commencing at the origin of the circumflex another large adherent thrombus was found occupying

¾ in. of the axillary artery. Beyond this point no further thrombosis was found either in the brachial or radial arteries of that side. Comparison of the right and left brachial arteries showed narrowing of the lumen of the vessel on the right side. The aorta, innominate and right and left carotid arteries were free from antemortem clot. The thoracic and abdominal viscera exhibited no important *pathological changes.*

The brain, together with its vessels at the base, was removed carefully, placed in 10 per cent. formalin to harden and then examined. A well-marked embolus was found at the division of the basilar artery into its terminal branches, and microscopical examination showed this to consist of partly digested fibrin with but few leucocytes and practically no recognisable red cells; it was obviously of antemortem origin. To naked-eye examination there seemed little obvious softening in the pons, crura, or occipital lobes, but histological examination of these various areas showed well-marked softening to the extent of extensive necrosis in the upper and mid pons and in the crura. We were unable to demonstrate a similar condition in the occipital lobes.

These findings, taken in conjunction with the clinical picture, suggest that the right clavicle (fractured no doubt during an epileptic fit and unnoticed by the patient) had at the time of the fracture or since, caused damage to the right subclavian artery resulting in thrombosis. The resultant embolus in the basilar artery is then readily explained by the escape of a fragment of the thrombus up the right vertebral artery, and this would seem to be the only explanation.

This case is obviously analogous to the two cases of cervical rib reported by Symonds,[1] although the actual cause was different; and it demonstrates that thrombosis of the subclavian followed by embolism of one of the cerebral arteries is the sequence of events in such cases, and so far as we are aware this had not been actually demonstrated by autopsy before. The thrombus in the subclavian had evidently existed already for several months. The practical point which emerges is that such conditions, though very rare, are liable to lead to cerebral embolism, and this liability emphasises the importance of immediate surgical intervention in those cases where cervical ribs or analogous conditions are showing signs of compressing the subclavian.

EPHEDRINE AND EPHETONIN.

By F. R. Curtis, M.B., Ch.B., M.Sc. Leeds.

(From the Department of Physiology, University of London, King's College.)

Ephedrine and ephetonin are now being fairly extensively used in the treatment of asthma, for they produce dilatation of the bronchi in the same way as adrenalin, though their effect lasts much longer than that of the latter. They are optical isomers, having the empirical formula $C_6H_5.CHOH.CH.CH_3.NH.CH_3$. The former is lævo-rotatory, and occurs in Ma Huang (*Ephedra vulgaris*); the latter is optically inactive, and has been synthesised in the laboratories of E. Merck, of Darmstadt, Germany.

Recently it was stated by Kreitmair[1] that ephetonin is as active, weight for weight, as ephedrine, in spite of the fact that ephetonin contains 50 per cent. of dextro-rotatory ephedrine, which is almost devoid of activity. These findings are not consistent with expectations derived from our knowledge of the behaviour of other optically active substances, as, for example, the hyoscyamines and adrenalin. Chen,[2] while admitting a qualitative similarity between ephedrine and synthetic ephedrine (ephetonin), found that in man the latter does not produce nearly so marked an effect on the blood pressure as ephedrine.

The experiments on which Kreitmair based his conclusions regarding the comparative activities of ephedrine and ephetonin are open to criticism. His method was to determine the relative effects on the blood pressure of decapitated cats of small doses of the two substances, the doses employed being 0·05 mg. per kilo.

Now, as Barger and Dale[3] pointed out, in the case of the relatively inactive amines, such small doses are quite unreliable quantitatively. Further, Chen and Meek[4] showed that ephedrine produces a transient tolerance, and I have found it impossible to obtain equal rises of blood pressure even using equal doses of the same substance. Chen regarded any attempt to settle the question by experimental methods as impracticable, but this paper sets forth the results of what may be called a statistical method of approaching the problem.

Cats, with brain and medulla destroyed, were employed as test animals, and the blood pressure was recorded by means of a mercury manometer attached to a cannula in a carotid artery. Advantage was taken of the fact that after small doses of adrenalin there appears to be very rapid recovery of the circulatory system to its previous state. Accordingly, a series of 12 cats was divided into three groups, A, B, and C, of four cats each. Each cat received as a first injection 0·4 c.cm. of a 1/10,000 solution of adrenalin hydrochloride. The animals of group A then received 4 mg. of ephetonin, those in Group B 2 mg. of ephedrine, and those in Group C 2 mg. of ephetonin. After each injection of adrenalin, ephetonin, or ephedrine, the rise of blood pressure was measured in mms. of mercury. It was then possible to obtain a ratio between the effects produced by adrenalin and ephedrine, or ephetonin. The following tables give the results obtained.

Group A.

—	Rise after adrenalin in mm. Hg.	Rise after ephetonin in mm. Hg.	$\frac{\text{Adrenalin rise.}}{\text{Ephetonin rise.}}$
Cat 1.. ..	96	86	1·1
Cat 2.. ..	146	132	1·1
Cat 3.. ..	92	64	1·4
Cat 4.. ..	115	132	0·8
Average ..	112	103	1·1

Group B.

—	Rise after adrenalin in mm. Hg.	Rise after ephedrine in mm. Hg.	$\frac{\text{Adrenalin rise.}}{\text{Ephedrine rise.}}$
Cat 1.. ..	136	120	1·1
Cat 2.. ..	124	130	0·9
Cat 3.. ..	138	124	1·1
Cat 4.. ..	128	108	1·2
Average..	131	120	1·1

Group C.

—	Rise after adrenalin in mm. Hg.	Rise after ephetonin in mm. Hg.	$\frac{\text{Adrenalin rise.}}{\text{Ephetonin rise.}}$
Cat 1.. ..	122	72	1·7
Cat 2.. ..	124	62	2·0
Cat 3.. ..	84	32	2·6
Cat 4.. ..	140	62	2·3
Average..	118	57	2·15

It is hardly necessary to point out that there may normally be quite considerable differences in the pressor responses of the different animals as expressed in mm. of mercury. For that reason adrenalin was used as a sort of index of the intensity of the circulatory reaction as compared with that produced by ephedrine or ephetonin.

From the tables it will be seen that compared with adrenalin, 4 mg. of ephetonin and 2 mg. of ephedrine give an equivalent effect, as would be expected from the fact that 4 mg. of ephetonin contain 2 mg. of ephedrine and 2 mg. of inactive dextro-ephedrine. The result receives further substantiation in the third table, where it is seen that 2 mg. of ephetonin (containing actually only 1 mg. of l-ephedrine) produces half the effect of 2 mg. of ephedrine.

---

[1] [Footnote for Kreitmair continues on a following page]

Summary.

Experimental evidence is submitted to show that ephedrine is approximately twice as active as ephetonin.

Medical Societies.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.

ANNUAL GENERAL MEETING.

THE eighty-seventh annual meeting of this Association took place on July 11th, 12th, and 13th at the West Riding Mental Hospital, Wakefield, Yorks, under the presidency of Prof. J. SHAW BOLTON.

Foreign psychiatric societies were represented by Dr. E. N. Brush (U.S.A.), Prof. Wimmer (Denmark), and W. Hans Evensen (Norway).

At the business meeting the following were elected honorary members: Dr. C. Hubert Bond. C.B.E., Dr. Eugen Bleuler (Zurich) and the Rt. Hon. Hugh Macmillan. P.C., K.C. The corresponding members elected were: Dr. Malcolm A. Bliss (St. Louis, U.S.A.), Dr. C. O. Ariens Kappers (Amsterdam). Dr. George H. Kirby (New York). Dr. Giacomo Pighini (Reggio, Emelia. Italy). and Prof. August Wimmer, (University of Copenhagen). Prof. C. E. Spearman was appointed the Maudsley lecturer for 1929.

The Gaskell gold medal and prize for 1927 was presented to Dr. Elizabeth Casson and that for 1928 was awarded to Dr. F. R. Martin. It was announced that H.R.H. Princess Mary, Viscountess Lascelles had been pleased to signify her willingness to accept the Association's nursing medal in gold and the certificate in mental nursing (honorary).

Prof. SHAW BOLTON took for the subject of his presidential address

The Evolution of a Mental Hospital: Wakefield, 1818–1928.

He said it was 19 years since the hospital provided a President of the Association, in the person of Dr. Bevan-Lewis. Wakefield could claim to be a mother of asylums, and it had reached a distinction accorded to but few. The first Wakefield Asylum opened in 1818. In 1853 the second was added, which accommodated 150 patients. The third was the modern building. Sir William Ellis who was the first director was afterwards at Hanwell. The President quoted at length from the old regulations. some of which showed much foresight, while others would now be regarded as humorous. The director was the superior officer, and he also acted as apothecary, surgeon, steward, and treasurer. Originally two visiting surgeons and two visiting physicians were appointed, but in 1821, probably on account of the confusion resulting from dual control, the visiting magistrates much increased the powers of the director and diminished those of the physicians. In the minutes of July, 1857, there appears a reference to Dr. Henry Maudsley, who was then on the Wakefield staff, and one of the earliest workers in the Wakefield Laboratory was Sir James Crichton-Browne. The latter not only fostered research in the institution, but he did his best to promote a general medical interest in the work and administration of the hospital. The appointment of resident clinical assistants, unpaid but having free board, lodging, and tuition, dates from early times.

The President proceeded to sketch the various additions to buildings, and the improvements in administration and treatment which were carried out in the progress of the years, discussing at some length the question of punishment of patients for gross misdemeanours. He added that since he took office mechanical restraint and punishment had ceased, both in fact and in name. He declared that if he had the authority he would render restraint of all kinds not only illegal but criminal on the part of any individual who ordered it without having first experienced its effects on his own person. He drew attention to the close association of the mental hospital with the University of Leeds and the advantages accruing therefrom, making particular reference to the establishment of the pioneer diploma in Psychological Medicine.

Sir ROBERT ARMSTRONG-JONES proposed, and Dr. J. BRANDER (Bexley) seconded, a vote of thanks for the address.

On Thursday, July 12th, Dr. M. J. MCGRATH (Wakefield) opened the day's proceedings with a paper on a description of the steps taken in a mental hospital to prevent the spread of dysentery and allied infectious diseases. He said it was essential to have isolation wards for new admissions and infected cases. Infection of inmates occurred not only through infected cases transferred from other places, but from new members of the staff. Hence every fresh patient and each new member of the staff was submitted to a special physical examination for infections. Of 467 probationers 83 had to be rejected as a result of the examination. The organisation of this work had led to good results. It was insisted that an institution entirely free of dysentery was peculiarly liable to infection from without, particularly if a foreign strain were brought in. Investigations led to the conclusion that periodic temporary immunisation of institutions in this respect was constantly taking place.

In connexion with this subject the PRESIDENT read a part of his Presidential address, postponed from the previous day, describing the seriousness of some of the epidemics of dysentery which at various times in the past had afflicted the inmates. The precautions now taken to detect and when found to isolate and treat thoroughly a case of bad diarrhœa or dysentery were given in detail.

Other Communications.

Mr. A. L. HOWDEN (Wakefield) read a paper and demonstrated the bacteriological methods employed at the hospital in regard to the detection of dysentery and allied infectious diseases.

Dr. J. R. LORD (Horton) spoke in praise of the modern skilled laboratory assistant, and said this was the first occasion he recollected on which one had read a paper before the Association. He congratulated Mr. Howden on his paper and demonstration.

Dr. F. A. PICKWORTH (Birmingham) said that at the Birmingham Mental Hospitals, in addition to isolating those who showed a positive Widal, they treated likewise all who had had contact or relation with typhoid patients, or who showed infective organisms in the fæces.

Dr. F. R. P. TAYLOR (Hellingly) said that at Hellingly dysentery cases came among the patients transferred from other hospitals, and it was not until regular bacteriological examinations were made the rule that real good ensued, though isolation had been previously carried out.

Prof. J. W. MCLEOD (Leeds University) expressed his surprise that Shiga infection epidemics did not occur in mental hospitals. He dealt with a number of points in technique.

Dr. C. HUBERT BOND said these communications must have brought home to everyone the necessity of having a laboratory attached to mental hospitals.

Dr. J. I. RUSSELL (York) referred to the different types of dysentery and the difficulties of differentiation.

Dr. LL. WYNN JONES (lecturer in psychology, Leeds University) read a paper on an investigation into the significance of perseveration. He said there were five kinds of perseveration—sensory, motor, ideational, emotional, and conative. He dealt only with the first three.

Prof. B. A. McSwiney (Leeds University) contributed a paper on Physiology in Relation to Psychological Medicine. He said that the paucity of information on cerebral function in the text-books was due to absence of methods available to investigate the normal activity of the higher nerve centres. The explanations advanced often took no account of the function of the lower nervous system in bringing about the requisite coördination and relationship between the different organs of the body. If knowledge of the physiological factors controlling mental activity was to advance, the physiologist must continue to make measurements on structures which he was able to control, and carry out investigations in which he was able to isolate the disturbing factors. He illustrated his thesis by a number of examples, many of which were illuminated by the work of Sherrington and others.

Dr. Ian Suttie (Fife) read a paper on Neurotic Superstructures in Certain Psychoses. The paper consisted of an elaborate justification of the treatment of early cases by psycho-analysis, and illustrated well the degree of concentration and patience required for the successful pursuit of this method.

The President followed with a lantern demonstration of the stages the egg passed through in the germination of the chick, bringing out well the final mechanism which resulted in the emergence of the chick into the outer world.

On Friday, July 13th, Dr. K. C. Paddle (Wakefield) read a paper on Review of Blood Pressure in the Insane. It was based upon the careful examination of 920 male patients, care having been taken not to excite the patient before or at the time of the examination. The cases were divided into seven groups. Summarising his results, Dr. Paddle said that in melancholia 51 per cent. of cases had a subnormal blood pressure; in mania 51 per cent. had a subnormal pressure; in epilepsy 70 per cent. had a subnormal pressure. The average blood pressure in the insane varied according to the age. The majority of insane epileptics had a constantly low pressure independently of the frequency of the fits or the kind of epilepsy.

Dr. F. A. Pickworth (Birmingham) contributed a paper on variation in the agglutinin formation in mental hospital patients and its probable relation to focal sepsis. The main purpose of the communication was a consideration of how the system might be invaded by organisms which demanded a considerable production of antibodies to effect their destruction and removal from the system. The organisms normally present in the jejunum evidently migrated to higher levels, as shown by examination of over 200 cases. The inter-relation between focal sepsis and the variation in agglutinin formation of the insane probably occurred through the medium of a high intestinal sepsis caused by infection with paratyphoid or food-poisoning organisms.

Dr. J. F. Smyth (Wakefield) spoke on the relation of the *Spirochæta pallida* to the histological changes in dementia paralytica. He said that spirochætes were found in 75 per cent. of the cases; they were found most frequently in cases which ran a stormy course. The number of cases examined was 52. The most that could be hoped for under treatment was an arrest of the damaging process to the cortex.

Dr. John Brander (Bexley) discussed general paralysis of the insane as a clinical and pathological entity.

Prof. W. H. Maxwell Telling (Leeds University) spoke of the value of psychical research to the physician. He declared he had received great benefit from a study of psychic phenomena, and proceeded to review the present state of knowledge and the tendency in the profession concerning this subject. His own attitude was sympathetic towards such subjects as telepathy.

The concluding item was a demonstration by the President on cases of sense deprivation and the primary importance of the aural centres in the cortex cerebri.

ANNUAL CONGRESS OF THE ROYAL SANITARY INSTITUTE.

PLYMOUTH, JULY 16TH–21ST.

The inaugural meeting on Monday has already been touched upon. During the remainder of the week the work of the Congress was, as usual, divided up among many sections. The following notes deal with some of the points of special medical interest which arose in the course of the meetings.

Hygiene in Industry.

Mr. Ramsay MacDonald, in his presidential address to this Section, compared the worker with a delicate scientific instrument; the old fashion of putting him to do a job just as it came was now abandoned by everyone who had any common sense. Public health had the individual as its aim, but the community as its medium, and included both self-help and mutual aid. The work of bodies such as the National Institute of Industrial Psychology, the Medical Research Council, and the Industrial Fatigue Board, was putting industrial hygiene in its proper place as one of the most vital concerns of our country. We were still in the transition stage and did not wholeheartedly accept the doctrine that the conduct of industry is a national concern. The latest attempts by the General Council of the Trade Union Congress to explore the conditions of industrial peace were an essential contribution to the practical success of recent scientific investigations. In industry strains, fatigues, and worries were as poisonous to life as were disease germs. A close and detailed study of the use to which the human body is put in industry was needed. Mr. MacDonald gave many convincing illustrations from the experience of Dr. C. S. Myers, of unnecessary fatigue and waste of muscular effort in factories, which had been easily remedied with a little study. The temperature and ventilation of workshops affected not only physical condition but the nerves, as shown by temper, general ease, and happiness. It had been found, also, that men varied in their suitability for working with machines running at different speeds; of two men working side by side at similar machines one might be brought to the verge of nervous breakdown by inability to keep up, while the other might complain of boredom from the slowness of the pace. The hygienist was handicapped by the fear of the worker that industrial economy meant intensification of labour for him. The solution of all such problems was of immense importance to industry both as regards its economic working and its internal harmonies, and this department of research was essential for moulding our organisation of industrial and sociological relations into a coöperative concord.

International Preventive Medicine.

Dr. L. Rajchman, Medical Director and Secretary of the League of Nations Health Committee, in his presidential address to the Preventive Medicine Section, outlined the policy and methods which had been evolved by seven years' work on the part of leading men of many countries of all continents. He referred to the services of epidemiological intelligence and public health statistics, of technical publications, and of permanent liaison work with national sanitary administrations; to commissions at work and organisations in progress in many countries; and to investigations of many problems, including those of sleeping sickness in Equatorial Africa, small-pox and encephalitis in Northern Europe, leprosy in South America and the East, malaria throughout the world. Other hopeful enterprises included the practice of preventive methods by health insurance organisations, the adoption of common standards for sera and vaccines, and common lists of causes of death, and the study of preventable causes of infant mortality.

The Present Position of the Tuberculosis Problem.

Dr. F. J. H. Coutts (Ministry of Health), in opening this discussion, pointed out that the conspicuous fall in the mortality-rate from 1851 to 1910 was at the age-period 20–25 years. Since 1910 the greater decline had been at later age-periods, while at age-periods 15–20 and 20–25 there had been little reduction among males and an actual increase in the female mortality. This disquieting feature of the breakdown of young adults from tuberculosis needed elucidation and investigation in each district. Much further investigation was also needed of the supposed immunity acquired by children who suffered from peri-bronchial or other mild forms of tuberculosis. He thought that direct measures had played their part in the decline of tuberculosis and quoted intensive experiments in Sweden and the U.S.A. in confirmation. As regards treatment, good results were being obtained from the induction of artificial pneumothorax and thoracoplasty, and the greatest sphere of usefulness of artificial light treatment was in the treatment of lupus.

Dr. Marcus Paterson said that we taught the infectious consumptive how to avoid infecting his own family and how to lead a healthy life, but we did not educate the public in the fact that the use of a pocket spittoon by the consumptive was a protection for them. Medical students, except in Edinburgh, did not receive adequate instruction in the management and treatment of tuberculosis.

Shell-fish.

The cultivation and marketing of shell-fish in good condition was dealt with from the point of view of the trade, of the Fishmongers Company, and of the medical officer of health. There appeared to be general agreement as to the great value of the bacteriological tests originated by the Fishmongers Company, coupled with inspection of the beds and an intimate knowledge of the topographical conditions.

Mr. James Y. Johnston (Prime Warden of the Company) described the action taken by his Company to organise an influential deputation to the Government, which had resulted in the appointment of special committees, one for investigation of the whole question of pollution of rivers and estuaries, and the other for instituting research as to sewage effluents.

Many medical officers of health spoke of the ready help afforded them by the Fishmongers Company in the case of doubtful shell-fish, and it was pointed out by Prof. J. W. H. Eyre that the Company receives samples for testing from all parts of the country, and that the information in its possession as to samples and beds is freely available both for the trade and for medical officers of health.

Housing.

The discussion on housing was opened by Councillor Albert Webb, chairman of the Plymouth Housing Committee, who dealt chiefly with methods of house-purchase, the renovation of existing privately owned houses, and the clearance of congested areas. He firmly believed in occupier-owners and, during the last three years, the Corporation had advanced £450,000 to enable tenants of limited means to become owners. The Corporation borrowed at 4¾ per cent., and lent at 5¼ per cent., and the ½ per cent. paid management expenses, so that this scheme was self-supporting.

The Corporation had also provided for the sale of municipal houses to existing tenants on easy terms. The only initial outlay for the tenant was a deposit of £10 and the cost of transfer and mortgage deed. For example, a "non-parlour" house, rented at 8s. 9*d*. per week, could be purchased by the payment of 9s. 6*d*. per week for 30 years.

The Corporation had renovated 147 properties under Section 3 of the 1925 Act, at a cost to the owners of £25,000, to be recovered from them in repayments spread over ten years. Most of this work was done by agreement with the owners. They had a new scheme, which was provisionally approved by the Ministry of Health, for reconditioning certain houses in a congested area and demolishing the remainder. Such a scheme might to some extent cater for the casual worker. An experiment in providing small houses for special cases was being considered.

Several speakers congratulated Councillor Webb on the housing activities of Plymouth. From all quarters came the admission that up to now nothing had been possible in the provision of houses for the poorest class and the low-paid worker with a large family.

Dr. C. Lander (Devonport) thought they should recognise that economic rents were frankly impossible, and that housing should be regarded as a State social service. There must be a subsidy and it should come from the National Exchequer. A valuable contribution came from Miss J. M. Upcott, housing manager to the Chesterfield Town Council, on the management of municipal housing estates on "Octavia Hill" lines. She advocated a gradual preparation and education of slum tenants for their removal to better quarters, with perhaps a transition period spent in reconditioned houses.

Milk.

Dr. W. G. Savage opened this discussion with a paper on Milk and Tuberculosis. He regarded the grading of milk as a "magnificent educational gesture." The Tuberculosis Order, as at present worked, was of no value whatever. It would be a continuing expense, with no reduction of bovine tuberculosis and no protection to the public from tuberculous milk. Before the country was committed to the expense of routine veterinary inspection of milk herds, they should be quite clear in their minds as to what they expected this inspection to accomplish and draw up a carefully thought-out scheme, including the coöperation of the dairy farmers.

In the discussion the case for dried milk was put by Mr. F. O. Morris, the case for pasteurisation by Dr. S. G. Moore, and there was a general admission that the eradication of tubercle was so remote that some method of rendering raw milk safe must be adopted in the meantime.

Immunity Methods in Scarlet Fever and Measles.

Dr. R. A. O'Brien showed that the Dick test, the Schultz-Charlton test, active immunisation, and the use of antitoxin have been firmly established in the case of scarlet fever. There was still lacking an antiserum to combat septic conditions which had already appeared, and the problem of the convalescent carrier or return case was unsolved. Convalescents were discharged with hæmolytic streptococci in their throats indistinguishable by any available test from scarlet fever streptococci, but it was not as yet practicable to ask for negative cultures before release, and the medical officer could only adhere to the rule of sending out cases after the restoration of normal health with an absence of discharges from mucous membranes. As regards measles, the utility of the serum of convalescents for conferring either temporary complete protection or for giving active lasting immunity, according to the date after exposure to infection on which the dose was given, was now accepted. The problem for sanitary authorities was to provide and maintain a supply of this serum and to make appeals for volunteer donors.

Dr. W. A. Lethem (Ministry of Health) pointed out that though last year measles killed five times as many children as scarlet fever, the public was still not convinced of its dangers. Schemes for the supply of the serum of convalescents were in operation in several towns in France, Germany, and the U.S.A. Dr. Lethem outlined a scheme for districts in this country. The serum was effective from the eighth to the fourteenth day after the temperature fell. It was preferable to obtain it from adults who could easily spare enough to immunise some 30 children. Adults were usually treated at home by general practitioners. The medical officer of health should hold a meeting with practitioners to explain the scheme and seek their coöperation in obtaining donors. He should select a laboratory and arrange for an expert from the laboratory to collect the blood. The serum remained potent for many months, if kept at a low temperature. He thought donors would be readily obtained when they understood the great benefit they were conferring on the community without harm to themselves. If the supply was limited, its use should be restricted to children for whom an attack of measles might be a matter of extreme gravity: if more ample, it might be used for all very young children who had been exposed to infection.

Dr. W. T. Benson (Edinburgh), Dr. J. Parlane Kinloch (Aberdeen), and Dr. E. H. R. Harries (Birmingham) confirmed from their experience the views expressed by Dr. O'Brien and Dr. Lethem.

Nursery Schools.

Miss Margaret McMillan described, with the aid of lantern slides, the wonderful changes effected in the pre-school children from the congested areas of Deptford and Greenwich by attendance at the Rachel McMillan open-air garden school. She explained the methods adopted and claimed that by economical management and simple buildings the cost is less than that of an ordinary infant school. The parents contribute, but in return the children get three good meals a day. Nursery schools may be a confession of failure—of failure under existing conditions to secure a good home for each child with reasonable access to playground or garden—but the practical sanitarian acknowledges that congested areas in our industrial towns will hardly be removed in one generation and that there is, in the meantime, a clamant need for many more "Rachel McMillan" schools run by enthusiasts like Margaret McMillan. It is not surprising, therefore, that the resolution, in favour of more open-air nursery schools, and calling upon local authorities to make the nursery classes in the Fisher Act of 1918 operative without delay, met with general acceptance by the Section. Prof. Winifred Cullis, in seconding, emphasised the fact that during these years the foundations of health, character, and education were laid, and that children who had been under the supervision of welfare centres showed fewer defects when they reached the school-entrance age.—Dr. Mabel G. Brodie also testified to the value of such nursery schools; and Dr. E. G. Annis (M.O.H., Greenwich) confessed that Miss McMillan's work for the children of his borough had converted him from a sceptic into a firm believer. The open-air régime and care taken quite prevented outbreaks of infectious disease in the school.

Light Treatment.

Dr. Albert Eidinow described the biological actions of light, while Dr. H. Stanley Banks (Leicester) and Dr. W. Allen Daley (Hull) dealt with the practical application of light treatment to public health work.

Dr. F. G. Bushnell (Devon) spoke on uses and abuses of light treatment, and all the three last-mentioned speakers sounded a note of warning as to exaggerated statements and commercial exploitation of this treatment.

Dr. Daley pointed out, from his experience, the danger of this treatment being added to the list of so-called medical baths and employed without proper medical supervision. He summed up by expressing the opinion that light treatment was a permanent addition to the disease-preventing and disease-curing methods which should be provided by a local authority, particularly for the sun-starved denizens of our towns, that the use of irradiated foodstuffs was not a substitute for light clinics; and that the provision of light treatment by baths committees should be watched with great care.—A resolution was adopted recommending the establishment of public sun and air bathing facilities by local authorities especially for children.

Health of Seamen.

Fleet-Surgeon W. E. Home said that during this year, for the first time, fairly accurate statistics of the mortality of seamen, occupied and retired, had been published by the Registrar-General. Their mortality from disease was 75 per cent., and from injury five times greater than those of "all males." The cubic space of British seamen had been increased from 72 cub. ft. to 120 cub. ft., while that of the lascars had remained at 72 cub. ft. Coincidently, the phthisis death-rate of British seamen had declined by 40 per cent., and that of the lascars only by 15 per cent. The seaman lived in his ship for 24 hours in the day, and his living accommodation should be passed by a health authority. Some of the seaman's needs were: care of water-supply, wash-places, good galleys, good w.c.'s, drying-rooms, and accommodation aft.—At a conference of port sanitary authorities, held on Thursday, July 19th, the following resolution was unanimously adopted:—

> That the Council of the Institute be recommended to direct the attention of the Government to the desirability of the care of the health of the men of the Merchant Service being placed in the charge of the Ministry of Health.

The motion was proposed by Fleet-Surgeon Home, and seconded by Alderman F. Askew, chairman, Hull and Goole Port Sanitary Authority, who together sent the motion up to the Council of the Institute, to get it on the agenda of the Conference. The motion was supported by Commissioner H. Miller, of the St. John's Ambulance Brigade, in an excellent speech, and its unanimous acceptance was ensured from the first.

National Health Insurance Service.

On the last day of the Conference Mr. Henry Lesser, in a presidential address, showed how financial considerations were retarding the proper development of the Service, and Mr. W. Gill Hodgson, clerk to the Liverpool Insurance Committee, expressed the opinion that the present scheme should be perfected by the addition of specialist and consultant services with laboratory aids and of dental treatment before any further classes of persons, such as dependants of insured persons, were brought in.

DONATIONS AND BEQUESTS.—Sir Henry Samman, Bart., of the Manor House, Willerby, Yorks, shipowner, left £23,000 for charity, including £10,000 to the Hull Infirmary, £5000 each to the Seamen's Mission, Hull, and the Henry Samman Chamber of Commerce Endowment, Hull, £1000 each to the Port of Hull Society Sailors' Orphan Homes, and to Hull Seamen's and General Orphanage, and £500 to Victoria Hospital for Children, Hull. —The Right Hon. Satyendra Prasanna, Baron Sinha of Raipur, of Delhi, India, and of London, left Rs.10,000 each to the hospital attached to the Belgatchia Medical College, the trustees of the Sadharan Brahmo Samaj of Cornwallis-street, Calcutta, the trustees of the Bhowanipur Sanmilani Brahmo Samaj, the Sambhunath Hospital, Bhowanipur, and the Calcutta Orphanage of Bulloram, Deys-street, Calcutta. And if he had not already made provision (as he had intended to do in his lifetime) for the maintenance of the Middle English School and Charitable Dispensary which he had built and for many years maintained at Raipur, then Rs.50,000 upon trust for investment and the income applied for such purpose.—Mrs. Emily Crossley, of Highgate, left £2000 to the Ancoats Hospital, Manchester, as to £1500 for the general maintenance of that hospital and £500 towards the general maintenance of the Convalescent Hospital at Warford, Cheshire, in connexion with the Ancoats Hospital.—Mr. Samuel Palmer Cooper, of Moseley, Birmingham, left £1000 each to the General Hospital, [illegible] the Birming- Birmingham, Queen's Hospital, [illegible] id to ham and Midland Free Hospital [illegible] and Dr. Barnardo's Homes; £500 ea[illegible] Midland Midland Eye Hospital, the Birmingham and Midland Homœopathic Hospital, the Birmingham Royal Institute for the Blind, the National Institution for the Blind, and the Children's Hospital, at Cold Ash, Newbury, if his niece, Mary Katherine Cooper, is matron there. After other bequests the ultimate residue of the property is left between the General Hospital, Birmingham, Queen's Hospital, Birmingham, the Birmingham and Midland Free Hospital for Children, and Dr. Barnardo's Homes.

Reviews and Notices of Books.

BIOLOGICAL INTRODUCTION TO THE STUDY OF NEUROLOGY AND PSYCHOPATHOLOGY.

Introduction biologique à l'étude de la neurologie et de la psychopathologie. By C. V. MONAKOW and R. MOURGUE. Paris: Félix Alcan. 1928. Pp. 416. Fr.80.

THOSE who endeavour to keep in touch with the philosophical background of biology are aware of the existence of a reaction against the confident mechanist and materialist theories of the last century. In the English-speaking world Prof. Whitehead, Prof. Lloyd Morgan, and General Smuts are among those now seeking to construct new biological concepts which shall be more adequate to explain the behaviour of living organisms. No biological hypothesis which aims at transcending pure mechanism can fail to be indebted to Bergson, who 30 years ago was a voice crying in a wilderness of determinism. Prof. von Monakow and Dr. Mourgue freely acknowledge this debt in the pages where they impugn current concepts in neurology and psychiatry on grounds which Bergson has rendered familiar. They state that pathological phenomena are considered in isolation from the organism; also that the existing conception of function is too static and ignores the time factor. They believe that evolution is not sufficiently recognised to be a qualitative as well as a quantitative change, and that language itself, owing to its mode of development, is unsuited to deal with the essential mobility of function. Owing to these disabilities modern neurology tends to see in pathological states of the nervous system no element save functional deficit, and does not take into account the compensatory efforts, evoked by injury from the organism, which distinguish living creatures from machines. To overcome these defects of method the authors find necessary new concepts which require new terms for their designation, and thus they introduce us to "klisis" and "ekklisis," "protodiakrisis," and "diaspasis," "hormétères" and "noohormétères," "syneidesis" and "hormè." The most important of these conceptions appear to be the two last named. "Syneidesis" is described as "conscience biologique" and is a principle of auto-regulation invoked to explain the efforts of an organism to compensate for its defects. "Hormè" is the undifferentiated drive from which instincts derive their impulsion and recalls Bergson's "élan vital."

Armed with these new weapons of thought Prof. von Monakow and Dr. Mourgue range over the whole realm of neural function from embryology to religion, and from the conception of causality to the permeability of the choroid plexuses. After an introductory chapter they trace the development of character in terms of the integration of instincts. The evolution of movement, orientation, and language is then considered. The authors next deal at length with disintegration of neural function, giving special consideration to aphasia, and severely criticising the theories of an anatomical localisation of speech "centres." Next come chapters devoted to the psychoneuroses and the psychoses, schizophrenia being taken as an example of the latter. The book concludes with a review of the evidence that abnormal permeability of the choroid plexuses plays a part in the ætiology of disease of the nervous system.

Criticism of this book is inevitably disarmed by the width of its scope, the laudability of its aim, and the ingenuousness of its title. The names of the authors are a sufficient guarantee that the theories developed are firmly based upon an expert knowledge of the histology of the nervous system and a wide clinical experience. That such authorities should be profoundly discontented with current physiopathological ideas is of considerable moment, and their attempt to provide a more truly biological basis for neurology and psychiatry cannot fail to be challenging and stimulating. How far they have succeeded in their object must be left to the decision of the individual reader. Those who are satisfied with a mechanistic physiology are unlikely to be led to alter their minds. Those who regard such concepts as inadequate to represent the living reality may perhaps find an effective substitute in "syneidesis" and its confrères. But many to whom such principles are incomprehensible will probably finish the book a little disheartened. Is it possible that owing to the structure of our minds and language we are of necessity condemned to employ scientific methods which can never tell us the whole truth about reality? Or may we hope with Prof. von Monakow and Dr. Mourgue that in time we shall succeed in forging new instruments of thought with which to enlarge our apprehension?

ANTHELMINTICS AND THEIR USES IN MEDICAL AND VETERINARY PRACTICE.

By R. N. CHOPRA, M.A., M.D. Cantab., Major I.M.S.; and ASA C. CHANDLER, M.Sc., Ph.D. London: Baillière, Tindall and Cox. 1928. With 5 plates and 65 figures in the text. Pp. xii.+291. 22*s.* 6*d.*

THIS book is written to display for medical and veterinary practitioners both recent and time-honoured methods of attacking helminths. The prime consideration in anthelmintic treatment, it is insisted, must be the patient's safety. The value or otherwise of diet and purgatives, the method of administration of the latter, and the criteria of cure are discussed. A chapter on helminthological considerations bears evidence of haste in preparation. The key which it contains, and which purports to deal, among other matters, with the commoner and more important adult nematodes parasitising man, is in many ways unsatisfactory. No mention is made of ascaris, trichuris, male threadworms, and the hookworms; the description of hydatid cysts seems to imply the necessary presence of scolices, and in the figures of ripe segments of *Tænia solium* and *T. saginata*, described as being drawn to scale, the scales are not correct. The statement that microfilariæ are injected by mosquitoes will not find general acceptance. Several proper names are confusingly misspelt. The chapter on correlation between the chemical composition and anthelmintic efficiency of drugs is a valuable one; full acknowledgement is made of the work of Caius and Mhaskar.

The use of various anthelmintics are considered in detail and this part of the book will be useful for purposes of reference. Most readers will turn to those drugs which are popular at the moment. It is suggested that carbon tetrachloride produces on the mucosa an anæsthetic protective action which limits absorption after doses of moderate size. The implication appears to be that small or divided doses must prove more dangerous than single doses of 3 to 4 c.cm. Evidence for this conclusion would be welcome. Commenting on the widely accepted explanation that poisoning attributed to this drug is really due to traces of carbon disulphide, the authors point out that this lacks laboratory evidence and that the dose of the carbon disulphide for a foal is 1 to 2 drachms. At the same time they accept the assumption that it is some sulphur compound which makes the drug toxic. The reservations which they advise in the administration of carbon tetrachloride entail a close personal examination of every patient. It is once more stated here that Schüffner and Vervoort advised oil of chenopodium in dosage of 3 c.cm.; reducing drops on the international dropper to cubic measurement, their dosage was really 1·2 c.cm. After noting that Ashford treated two million cases with thymol without a single fatality, the authors state that chenopodium and carbon tetrachloride are less dangerous than thymol for field work (though the records of neither approach in safety this cited example) and have largely supplanted thymol in the hands of most practitioners who have kept abreast of the times. We deprecate the implication that the many authorities who favour treatment by thymol are old-fashioned. The chapters on antimony and emetine used mainly in schistosomiasis, are valuable.

The book as a whole is uneven, but since it reflects the views of men who have had considerable experience in the use of anthelmintics it will be studied with interest by those practising in the tropics.

SHORT ESSAYS ON MEDICAL TOPICS.

By C. O. HAWTHORNE, M.D. London: John Bale, Sons and Danielsson, Ltd. 1928. Pp. 246. 4*s.* 6*d.*

THIS little book contains some 50 essays, from which it will be gathered that many of them are not longer than the average leading article. Hence, as the subjects dealt with vary extremely, not only in theme but in importance, there are places in which the author is driven to being arbitrary, for he has allowed himself so little space in which to explain his views and no space at all for argument with those who might differ from him. But we do not think that many will want to differ, for the author, in discussing some of the most important professional topics, has dealt with them fairly, brought out the salient points, and delivered well-balanced judgments.

SECTION-CUTTING.

An Introduction to the Technique of Section-Cutting. Edited by FRANCES M. BALLANTYNE, M.A., Assistant in the Zoology Department, University of Glasgow. Edinburgh: E. and S. Livingstone. 1928. Pp. 80. 3*s.*

THIS little book has been compiled from the notes of the late Mr. Peter Jamieson, for many years assistant in the department of zoology in the University of Glasgow. It sets forth clearly and briefly the basal technique of section-cutting, and will no doubt find a place in the junior student's library. It is, however, quite elementary, and while, within its limits, its teaching is admirable, it contains little more than the student can learn from an hour's personal instruction and a little practice. If a medical student decides to be content with this manual in place of a more ambitious work he should disregard the statement on p. 49 that formalin as a fixative is only satisfactory for such objects as the eggs of frogs and newts.

KALA-AZAR.

A Handbook for Students and Practitioners. Second edition. By L. EVERARD NAPIER, M.R.C.S., L.R.C.P. Lond., in charge of Kala-Azar Research, Calcutta School of Tropical Medicine. London: Humphrey Milford, Oxford University Press. 1927. Pp. 203.

To those who practise in England kala-azar is merely of academic interest; but to the student of tropical medicine this disease is of paramount importance, for it is one of the dramatic infections of the tropics of which our knowledge has made rapid strides during recent years. Only some 16 years ago kala-azar was regarded as inevitably fatal; and now we learn it is possible to predict a cure in over 90 per cent. of cases. The second edition of Napier's Kala-Azar is thus opportune. Into its 200 pages a vast amount of information is compressed. Especially valuable is the account of the minute epidemiological investigations which led up to the modern conception of the transmission of the disease by *Phlebotomus argentipes.* These demonstrate clearly what can be accomplished by systematically applied observations in a limited area such as the town of Calcutta. The tropical practitioner will welcome a reasoned account of the treatment of kala-azar by the newer pentavalent compounds of antimony; he will, moreover, appreciate the numerous clear illustrations and graphs and the exhaustive bibliography.

ANAEROBES.

Données récentes sur les microbes anaérobies et leur rôle en pathologie. By W. WEINBERG and B. GINSBOURG. Paris: Masson et Cie. 1927. Pp. 291. Fr.35.

Weinberg and his colleague have performed a great service to bacteriologists in publishing this review of the work on anaerobes published between 1918 and 1926. The review is accurate, comprehensive, and is informed throughout with the authors' profound knowledge of the subject. The bibliography contains some 1400 references. If there is a fault it is that certain organisms are included which may fail to stand the test of further investigation; but this is better than omitting any which subsequently prove to be of importance. Bacteriologists will be grateful to the authors for such an excellent work of reference.

JOURNALS.

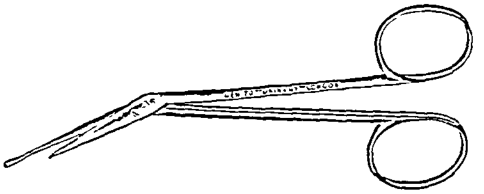
THE CRIPPLES' JOURNAL. Vol. V. No. 17. July, 1928. 1*s.* 6*d.*—The publication of the April number of this journal closed four years of work, and the present issue inaugurates the passing of the journal from being the official organ of the Central Council for the Care of Cripples into an independent publication run by its own advisory council and with definitely international aspirations. This advisory council, presided over by Sir Robert Jones, will be composed as follows: Dame Georgina Buller, Dame Agnes Hunt, Mrs. Townsend, Sir William Wheeler, Sir John Lynn Thomas, Rev. Ratcliffe Barnett, Sir William Lawrence, Bart., and Mr. A. H. Wood (Great Britain), Mr. Edgar Allen and Dr. Robert Osgood (America), Dr. Calvé (France), Dr. Murk Jansen (Holland), Prof. Putti (Italy), Dr. Rummelhoff (Norway), and Dr. Biesalski (Germany). The policy of the journal will be towards promoting unity of effort in bodies already dealing with one field of social work or another in connexion with the interests of cripples, and it is intended to provide information regarding all work in other countries bearing on this policy, and to print articles with the special object of instructing voluntary workers in clinical and training centres. Much stress will be laid upon the publishing of articles of an educational nature while, if the financial future of the journal allows, the price will remain at its present modest figure. We wish our contemporary all prosperity in its ambitious departure.

New Inventions.

PROBE-POINTED SCISSORS

FOR USE IN REMOVAL OF SALIVARY CALCULI.

IN removing calculi impacted in Wharton's duct, I have found the probe-pointed scissors here illustrated extremely useful. The probe is introduced into the duct as far as the stone, the scissors then lay open the duct, when the stone is usually extracted without difficulty.



The instrument has been made for me by the Genito-Urinary Manufacturing Co., 28A, Devonshire-street, W.1.

EPIDEMIC CONSTITUTION.

FREIHERR VON PIRQUET'S discovery of the skin reaction to tuberculin not only enabled us to realise the universality of tuberculous infection, but has also proved to be the forerunner of a series of investigations of a similar character which have brought within the compass of one scientific theory most of the epidemiological phenomena exhibited by a large group of the acute communicable diseases. The Schick and Dick tests, although the significance of a positive result is different from that in Pirquet's reaction, have been equally fruitful in the genesis of ideas as to the prevalence of the infections of scarlatina and diphtheria, and these ideas have been found applicable to the epidemiological problems of other droplet-borne infections, such as poliomyelitis, meningococcal meningitis, and epidemic encephalitis. Prof. ULRICH FRIEDEMANN'S paper, published on page 211 of our present issue, is an admirable survey of the present state of knowledge in relation to the ætiology of some of these diseases and the extent of latent infection with the virus, whether known or still undetected, of some of these diseases among civilised communities. The essential truth now established is the extent to which the population is constantly immunised, presumably by subminimal doses of the virus, against diphtheria and scarlet fever, a process which Prof. FRIEDEMANN terms "latent epidemisation." The meaning of this phrase has been tersely explained by W. L. AYCOCK[1] in these words, "Of susceptible individuals exposed to measles 1 out of 1 develops the disease; to diphtheria 1 out of 10 develops the disease and 9 out of 10 develop subclinical immunity; to poliomyelitis 1 out of 100 develops the disease and 99 out of 100 develop subclinical immunity, or immunity from abortive attacks." Students of epidemiology will subscribe generally to this view without committing themselves to acceptance of the numerical proportions, and there can be no doubt that the way to this state of agreement has been paved by the American workers on the dermal reaction to diphtheritic and scarlatinal toxins. At the same time, it is only right to remember that ideas of this nature, nebulous perhaps, like many ideas born of clinical observation, found expression long before they were capable of experimental verification, in explanation, for instance, of such facts as the observed immunity of fever hospital residents and nurses without the affliction of previous manifest disease, a peculiarity in relation to scarlet fever and diphtheria contrasting markedly with the behaviour of unvaccinated members of the staff in contact with small-pox. Indeed, it may be said that clinical observations, field inquiries, and statistical surveys had already made the minds of epidemiologists receptive to the idea of "latent epidemisation" and "latent immunisation," although the theory had not actually been given its present acceptance and wide application.

Since FARR made a science of vital statistics English epidemiologists have continued to search for the laws of epidemics, and many of the proceedings of the Epidemiological Society, which is now merged in the Royal Society of Medicine, will repay study to-day. The periodicity of the different zymotics, their incubation periods, age-incidence, and variable case-mortality in relation to the apparent source of infection, the course and peculiarity of single epidemics, the predictability of their behaviour, were all explored for the clue which would lead to the discovery of one thing common to them all, the law which governed their coming and going. FARR brought the art of epidemic prophecy to a high state of accuracy, and satisfied himself by purely mathematical reasoning that there was more behind the decline of an epidemic than mere exhaustion of the number of susceptibles existing at its onset. In more recent years attempts have been made to account for the decline and recurrence of epidemics by variation of the infectivity of the virus, a theory not inherently improbable since changes in virulence are well recognised. Perhaps the most ingenious mathematical attempt to correlate the seasonal and other variations of the incidence of epidemic disease was the application of the periodogram to this type of problem by BROWNLEE.

Working alongside the statisticians—sometimes combining more than one function in a single person—were the bacteriologists and the practical sanitarians, both piling up observations which undermined the old conception of the epidemic without supplying enough material to provide entirely new foundations. The bacteriologist established the existence of chronic or intermittent carriers of infection; the practical investigator of epidemics was more impressed with the importance of mild, anomalous cases of disease. But it was really the field observations of J. A. GLOVER and S. F. DUDLEY, followed by the laboratory study of epidemics in mice by W. W. C. TOPLEY, which established the paramount importance of the population-medium—its constitution, its spacing, its internal movement, and the influx of new members—as controlling factors in the rise and fall of epidemics. Flagrant disease, anomalous disease, *infection without* disease, intermittent and chronic carrier states are now seen in their true importance and interrelation with one another, and the reactions of Schick and Dick are measures of their combined influence. Many things still remain to be explained, notably the tendency for diseases practically to disappear and then revive with apparent irregularity and with impressive suddenness, like influenza and poliomyelitis, in the absence of abnormal migration, or to occur apparently de novo as in the case of epidemic encephalitis. But we have a solid addition to the body of medical thought in this new theory of the epidemic, which justifies the best part of the established measures for control of the communicable diseases, while revealing the reasons why these in themselves have proved insufficient to abolish the endemic zymotics from civilised communities. The criteria of communicability, too, have been extended, and we can no longer assume that diseases like rheumatism are non-communicable merely because case-to-case associations are untraceable. Further, we have been armed with a new specific preventive in the form of toxin or toxin-antitoxin inoculation, the value and limitations of which are well stated in Prof. FRIEDEMANN'S paper.

THE VACCINATION REPORT.

EARLY this week appeared the Report of the Committee on Vaccination appointed two and a half years ago by the Minister of Health in conjunction with the Medical Research Council. It was a Committee of seven with Sir Humphry Rolleston as chairman,

---

[1] Amer. Jour. of Hygiene, January, 1928, p. 35.

Dr. J. R. Hutchinson as secretary, and Dr. F. R. Blaxall, Dr. G. F. Buchan, Dr. A. E. Cope, Dr. Mervyn Gordon, Prof. J. C. G. Ledingham, and Dr. J. R. Perdrau as members. The Committee was asked to inquire and report: (1) on matters relating to the preparation, testing, and standardisation of vaccine lymph; (2) on the practical methods which are available in the light of modern knowledge to diminish or remove any risks which may result from vaccination; and (3) on the methods of vaccination which are most appropriate to give protection against risk of small-pox infection in epidemic and non-epidemic periods. The Committee was at the same time given liberty to coördinate the work of investigation on these questions in this country and abroad. The Report is divided into two parts, of which the first deals with each reference in turn, and the second exclusively with the consideration of the nervous conditions which occasionally follow vaccination. A series of appendices complete a volume[1] of 324 pages, which is admirable alike in its lucidity and restraint.

The Committee's reference has given rise to an account of the methods of lymph production in general and especially those employed by the Government Lymph Establishment. The preparation of the vaccine is of peculiar interest, for, with the exception of the original Pasteur method of treatment of hydrophobia, small-pox vaccination is to-day the sole established instance of the use of a living virus as an immunising agent. Although strains of vaccine lymph of diverse origin are used, the vaccination process throughout the world is remarkably constant in character and uniform in feature, and agreement has been reached as to the methods of testing the potency of lymph and as to the minimum standard of potency which can be sanctioned. These tests and standards are now laid down in the Regulations under the Therapeutic Substances Act, and they give, in the Committee's opinion, the desired assurance that the preparation of vaccine lymph is being carried out on approved lines as regards minimal potency and comparative absence of associated micro-organisms. Government lymph, it is interesting to note, is not issued until about two years from the date of its collection, when, owing to the combined action of the glycerine and oil of cloves the extraneous organisms it contains are eliminated or reduced to 5 or less per mg. There is still, unfortunately, a great lack of information as to the minimal dose of lymph necessary to secure adequate immunity from small-pox, and this is a problem awaiting solution by experimental means. Singular promise lies in an observation recently made at the Lister Institute, where vaccine virus, in contact with chick embryo cells, has been found to increase in potency one-thousand fold. Otherwise there is a general consensus that different strains have similar immunising powers. Vaccination in this country has hitherto aimed at securing in infancy the longest possible duration of immunity and at postponing the time when revaccination should become necessary, whereas the American and Canadian practice is to popularise vaccination by rendering it as little incommoding as possible, with the hope that a second or even a third vaccination will not merely be tolerated, but even sought. The Committee now definitely recommends that, in place of the officially advocated four insertions, a trial should be made of vaccination and revaccination in one insertion with a minimum of trauma, and deprecates multiple scarification or cross-hatching. The optional age for vaccination on these lines is regarded as 2–6 months, and the offer of revaccination might with advantage be made when the child enters school at 5–7 years, and again on leaving it at 14–16 years. Multiple insertion would still be available for such persons as desire to obtain the maximum protection at one stage. Vaccinators are advised to inspect twice after vaccination, the second time between the fourteenth and seventeenth days, and to make it clear to parents that such medical attention as is required is obtainable without cost. The syllabus of instruction to medical students should, the Committee feels, be revised in the light of present-day knowledge.

The risks of vaccination have markedly diminished since the Act of 1898 came into force, and in so far as the risk is from sepsis it is likely to diminish further to a vanishing point. But the second part of the Report is, as we have said, given up entirely to the risk from disease of the central nervous system following vaccination, and there might appear to be a certain want of proportion in devoting more than 100 pages to this subject, were it not for the fact that the occurrence of post-vaccinal nervous disease, however seldom of occurrence, cannot fail to have a bad effect on vaccination both in its administrative and in its medical aspects. Happily the Committee is able to point out the extreme rarity of such manifestations. During a period of five years (1922–27), in which 3 million charges of lymph were issued by the Government station, and the estimated number of vaccinations performed in this country was over 4½ million, 51 deaths were recorded from this cause. Particularly rare is nervous complication after revaccination and after primary vaccination in early infancy, and on this ground, if on no other, early infancy remains the time of choice for primary vaccination. Here is incorporated, at length, the report of the committee appointed in 1923, under the chairmanship of Sir Frederick Andrewes, which now sees the light in this country for the first time. Although the non-appearance of the Andrewes Report may have occasioned undue anxiety in some quarters, justification of the delay lies in the reassuring commentary which now appears in the light of further knowledge. The Rolleston Committee unanimously acquits vaccinia virus of being the sole cause of nervous sequelæ, although it cannot exonerate vaccination from playing some part in their causation. It is its considered opinion that the coöperation of vaccinia with the viruses of poliomyelitis or of encephalitis lethargica, or possibly some unknown neurotropic virus harboured by a vaccinee, must for the present be retained as a working hypothesis of causation. It is hoped that the publicity now given to this complication will result in an accumulation of clinical and epidemiological data which may help along with experimental research to solve a problem of great importance in quality if not in quantity.

The final recommendation is to the effect that steps be taken to impress upon the public mind the nature and purpose of vaccination. The Committee's Report will afford the medical profession for the first time a body of accurate and unbiased information to be used for this purpose, and we believe with good prospect of success.

ANTHROPOLOGY AND PARASITES.

THE nasty grey squirrel which came from North America and escaped from the Zoo some years since to spread all over England, as far north as Yorkshire, and at least to the Cotswolds in the west, carries with it everywhere its own special flea; anyone knowledgeable in such matters (whether he should be called a pulicophile or a siphonapterologist we do not know) who picked up a dead *Ceratophyllus wickhami* in the road would be sure that *Sciurus cinereus* was not far off. And this is the general truth about parasites; each species is adscript to one or at most two or three hosts, and very few are so little particular in their habitats that they range indifferently over a large number. When the hosts travel they take their parasites with them. It is very unlikely, for instance, that the great plague vector *Xenopsylla cheopis* is autocthonous in England; it lives, or used to live, on the rats in the Borough because it had come with its host from the tropics. Similarly, the provenance of the labourers on the coffee plantations in Brazil can be predicted by finding out whether their predominant hookworm is *Ankylostoma duodenale* or *Necator americanus*. This segregation and isolation of parasites in particular hosts naturally encourages speciation—i.e., separation into distinguishable forms—and their occurrence may give us some information both as to where the host has been quite lately and as to where and what the hosts' ancestors have been in the remote past. The specific differentiation of human lice as they occur now is dubious and uncertain; it is supposed that they are largely mixed hybrids of some definite species which used to occur isolated on the primary human races, and which have become mixed by human migrations and intercourse.

---

[1] Ministry of Health. Report of the Committee on Vaccination. Cmd. 3148. H.M. Stationery Office. 1928. 7s.

In one way and another, therefore, parasites may throw light on a good many general questions, and in the last number of the *Quarterly Review of Biology* (vol. iii., p. 225) the possible evolutionary significance of the protozoan parasites of monkeys and man is discussed in an interesting way by Prof. ROBERT HEGNER, of the Johns Hopkins School of Hygiene. He recognises six amœbæ, seven flagellates, one coccidium, and one ciliate as being genuinely parasitic in the human intestine, of which *Entamœba histolytica*, *Isospora hominis*, and *Balantidium coli* are definitely pathogenic: in the blood we have three malarial parasites, three trypanosomes, and three *Leishmania*. The protozoa of monkeys are naturally not nearly so well known, and it is obvious that observations on animals living in captivity in close association with man are not of much significance. The monkey amœba *E. nuttali* is as like the human *histolytica* as it can be, nor can their harmless *E. coli* be distinguished from those found in man. And with the exception of the *Leishmania* the same correspondence is found in the other groups; 11 out of 15 of the human genera, and two-thirds of the human species have been described from monkeys, though the malarial parasites of monkeys would be better described as very similar to, rather than identical with, that of man. The facts are interesting; their interpretation is difficult, for such a situation may have arisen because man has a genetic relationship with monkeys or because he provides in his bowels, his blood, and his economy in general, a similar series of habitats. On either hypothesis human parasites would be more like those of monkeys than those of rats or cows, and there seems to be nothing in the argument which would convince a determined fundamentalist of error. On the whole, the genetic relationships of hosts and parasites are not very close, and if the occurrence of monkey parasites in man indicates the line of human descent, what significance are we to attach to the discovery of *Balantidium coli* in pigs and guinea-pigs or to the fact that the other natural host of *Pulex irritans* is the badger?

Annotations.

"Ne quid nimis."

THE BUNDABERG REPORT: FATAL STAPHYLOCOCCAL INFECTION.

THE report of the Royal Commission on the Queensland serum tragedy of last January[1] has now been tabled in the Federal Parliament. The findings of the Commission are these:—

The Findings.—1. The injections of toxin-antitoxin mixture administered by Dr. Thomson at Bundaberg on Jan. 27th, 1928, were responsible for the deaths of 12 out of 21 children inoculated, and for the illness of several who survived.

2. The toxin-antitoxin mixture as issued by the Commonwealth serum laboratories was properly prepared and sterile, but contained no antiseptic, and, therefore, did not prevent the growth of micro-organisms accidentally introduced into it.

3. The rubber-capped bottle of toxin-antitoxin supplied to Dr. Thomson at Bundaberg was accompanied by no information as to the presence or absence of antiseptic.

4. The omission of antiseptic was intended to safeguard against the dangers attendant upon freezing, but the issue of this preparation without antiseptic in rubber-capped bottles suitable for repeated usage is an unsound procedure.

5. The toxin-antitoxin mixture in the bottle used by Dr. Thomson was contaminated by him with a pathogenic staphylococcus during a series of inoculations on Jan. 17th, 20th, 21st, and 24th, most probably on the last occasion.

6. The consideration of all the available evidence concerning the deaths at Bundaberg points to the injection of living staphylococci as the cause of the fatalities.

As a result of much experimental work and a critical review of the evidence, the Commission was led to make certain definite recommendations with a view to avoidance of similar tragedies in the future.

The Recommendations.—1. That biological products in which the growth of pathogenic organisms is possible should not be issued in rubber-capped containers for repeated use unless there is present in the material a sufficient concentration of antiseptic to inhibit bacterial growth.

2. That all biological products not containing antiseptic, however issued, should bear a conspicuous printed notice, both on the container and on the package, to the effect that no antiseptic is present; that they should be used immediately on opening, and any remaining product discarded.

3. That biological products should be distributed in bottles or ampoules of clear glass in which it is easier for the medical practitioner himself to detect turbidity or any other defect.

4. That the Commonwealth Department of Health should make full and careful inquiry as to whether it be advisable to substitute anatoxin or some similarly modified immunising agent for toxin-antitoxin.

5. To ensure the adoption of the most approved technique, facilities for special post-graduate training should be afforded to all medical officers entrusted with the conduct of public campaigns to diminish the incidence of disease by immunisation.

Poisoning by diphtheria toxin, it will be noted, is excluded on adequate grounds. The clinical picture in the fatal cases was not that of fatal diphtheritic toxæmia: at the autopsy the suprarenal glands were found to be normal, and the children who recovered did not show any of the characteristic sequelæ of diphtheria. No free toxin was found in the prophylactic remaining in the fatal bottle nor in many duplicate bottles taken from the batch of prophylactic incriminated. The possibility of tetanus was carefully considered and rejected. The evidence for staphylococcal infection was that the remaining fluid in the bottle used was noted as cloudy on the day after the injections, that the contamination had "almost certainly" occurred three days before the fatal injections were given, and that the remaining fluid in the bottle yielded a pure culture of staphylococcus. Of the 21 children injected 12 died; in all 9 survivors, of whom 6 were ill, abscesses developed at the site of injection, and from 5 of these abscesses a staphylococcus apparently identical with that in the fatal bottle was recovered in pure culture. The estimate is that five million cocci, together with their products of growth, were injected into the children. The children began to suffer within six to eight hours from vomiting, diarrhœa, fever, early unconsciousness, retention of urine, and, in the younger ones, convulsions, death occurring within 24 hours in several instances. With two doubtful exceptions no metastatic staphylococcal abscesses developed in any of the survivors. The coccus isolated did not seem to possess any unusual cultural or fermentative properties and closely resembled varieties of *Staphylococcus aureus*, though it produced "a buff coloured" and not "a typically orange" deposit. An antiserum to the coccus agglutinated aureus strains typically. Apparently neither culture nor filtrate produced in laboratory animals, including *Macacus rhesus*, a picture resembling that seen in the children, though small doses given intravenously to rabbits killed in 12 to 24 hours with convulsions. Evidently higher monkeys were not available for injection. The Commissioners very fairly state that their findings are based on evidence that is suggestive rather than conclusive, that unfortunately defects in the clinical study of the cases and lack of specialised bacteriological and pathological examination of the children who died left serious gaps in the evidence, and that "short of the unthinkable experiment of injecting the living staphylococci into children, it is not possible to offer rigid proof . . . for there is not within our knowledge any previous experience of the subcutaneous injection of large numbers of living staphylococci into young children." Bacteriologists, we think, will agree that the Commission could not do otherwise than conclude that the contaminating staphylococcus and its toxins caused the deaths, and that the tragedy would have been avoided had the prophylactic contained sufficient antiseptic, a practice which is probably universal in England, America, and the Continent. So far as we can find, there are on the English market no prophylactic preparations without adequate antiseptic. On such points the Therapeutic Substances Act provides for any control considered necessary.

---

[1] THE LANCET, 1928, i., 249, 1293.

Two other points in the report merit attention. The Commission recommend inquiry directed towards the replacement of toxin-antitoxin mixtures by toxoid or anatoxin. No reasons for this recommendation are given in the text of the report available at the time of writing. The needles used in immunising the children had apparently been kept in methylated spirit. The phrase "sterilised in methylated spirit" occurs in the report. It is well known, and has been emphasised by T. J. Mackie[2] in a recent important review of the preparation of catgut, that methylated spirit possesses a restricted bactericidal power and that it cannot be relied upon to sterilise surgical apparatus if resistant or spore-bearing microbes are in question.

THE TRAFFIC IN NARCOTIC DRUGS.

In accordance with a precedent initiated last year, the annual report of the British Government to the League of Nations (1927) on the traffic in opium and other dangerous drugs, has been communicated to the press. It deals with the administration of the Dangerous Drugs Acts, 1920 and 1923, in Great Britain, and furnishes abundant statistical information as to the manufacture in this country of morphine and heroin and their salts, and as to the import and export of opium and its alkaloids, and of cocaine during 1927. Reference is made to the extent of the international illicit traffic alluded to in THE LANCET of July 21st (p. 133). While several seizures of drugs were made at English ports on ships of British nationality, it is satisfactory to learn that no information had been received that any firm in Great Britain had been engaged in smuggling drugs abroad, nor have any seizures of drugs of British manufacture been reported during the year. It may be well worthy of consideration whether, if all members of the League of Nations and States parties to The Hague Opium Convention of 1912 had passed—and enforced—legislation like the Dangerous Drugs Act, 1920 and 1923, which gave effect to that Convention, the international situation in regard to the commerce in narcotic drugs would not be more satisfactory than it is. The amount of British morphine manufactured and exported continues to fall. While a few years ago some 14 tons were in one year exported, in 1927 the amount was 66,107 oz. The figures for heroin are less satisfactory, 17,427 oz. having been manufactured against 11,113 oz. in 1926; 11,165 oz. were exported against 6799 oz. in 1926; 4673 oz. were consigned to France, a considerable increase on the amount for 1926. Of 107,042 lb. of raw opium arriving through the approved ports of London, Liverpool, and Southampton, no less than 86,080 lb. came from India, and only 19,888 lb. from Turkey. As the morphine content of the Indian drug was 10·98 per cent., against 11·12 per cent. in the Turkish, the old prejudice against the pharmaceutical use of the Indian variety, by reason of its alleged poverty in the alkaloid, appears to have been ill-founded. Hitherto there has been no production of cocaine from the leaves, or by refining crude cocaine, in Great Britain, but in 1927 a licence was granted to Messrs. May and Baker, Ltd., of Wandsworth, to carry on experiments in such manufacture. The licence precludes the marketing of such produce without the special sanction of the Home Office.

Two important seizures of cocaine have been made in London this year, one of Japanese manufacture smuggled in by a Lascar on a vessel from the Far East; the other of German manufacture exported to Lithuania and thence smuggled in by a Lithuanian resident in London. There were 60 prosecutions under the Dangerous Drugs Act in 1927; 45 persons were convicted and fined, or imprisoned, or dealt with under the Probation of Offenders Act, while five were recommended for deportation. It appears that a considerable amount of morphine (65,746 oz.) was used in 1927 for the manufacture of codeine. This alkaloid is not scheduled as a dangerous drug, although in the first draft of The Hague Convention it was included. The question of applying to it the provisions relating to morphine and heroin has engaged the attention of the Opium Advisory Committee at Geneva.

ACUTE EMPYEMA.

In a recent article on the treatment of acute empyema, Dr. Antoine Basset maintains[1] that there is no longer any uniformity of method in dealing with this condition, nor is there any soundly established doctrine to guide the practitioner when faced with this emergency. Prior to the epidemic of influenza in 1918, the treatment of empyema was similar to that of any other collection of pus—viz., immediate evacuation and drainage. To render these more effective, costal resection was usually practised. The customary method was adopted for the treatment of empyema complicating broncho-pneumonia during the earlier months of the pandemic, but the results were profoundly disappointing. In certain of the American military camps the post-operative mortality is said to have reached the figure of 84 per cent. As a consequence less drastic methods were advocated: aspiration with irrigation of Dakin's or Murphy's solution replaced the classical operation of costal resection and open drainage. The advantages to be derived from conservative treatment, at least as a temporary measure, were discussed at the Twenty-third Congress of the French Surgical Association in 1920, and the matter has been debated ever since. Dr. Basset advises postponement of operation when empyema complicates acute pulmonary disease; in such cases he considers it advisable to wait until the pneumonic process shows signs of retrogression. Meanwhile the patient may be relieved by aspiration of pus and supported by medical treatment, including vaccine and serum therapy. When operation is decided on, a local anæsthetic should be used and as a rule the most effective drainage will be secured by resecting 4 or 5 cm. of the tenth rib in the posterior axillary line. Pneumococcal empyema in children is often a relatively benign infection, and for these cases repeated aspirations may suffice. They are certainly to be preferred during the acute pneumonic stage. Rib resection should also be avoided in early childhood—i.e., before the age of 18 months. But there is an exception to the statement that in the presence of an acutely diseased lung preliminary treatment by aspiration is the method of choice. A putrid empyema, or one associated with gangrene, should be freely drained at the earliest possible moment whatever the condition of the subjacent lung. Dr. Basset lays stress on the importance of a careful cleaning of the empyema cavity by gauze swabs at the time of operation. Neglect of this precaution may lead to blocked tubes and ineffective drainage. Short wide tubes should be used and the employment of a Tiegel's valve will permit free exit of pus while preventing the entrance of air during inspiration. A simpler method of attaining the same end is, of course, to connect the drainage-tube with a reservoir containing antiseptic solution.

INTESTINAL BACTERIA IN PERNICIOUS ANÆMIA.

IT is rather more than 20 years since Dr. C. H. Herter pointed out that *Bacillus welchii* was abnormally abundant in the fæces of cases of pernicious anæmia, and rather before that time Dr. William Hunter began to urge the ætiological importance of gastric and intestinal streptococci. Both organisms are hæmolytic in the sense that they can produce extracellular toxins which are capable of dissolving red corpuscles both in vitro and in the body of experimental animals. The capacity of *B. welchii* in this respect is especially powerful, and Dr. H. G. M. Henry and others have worked out the conditions under which its hæmotoxin is produced, how it acts in the body, and how it stimulates the production of an antitoxin. That the chronic anæmia of pernicious anæmia is directly due to any such antigenic hæmolysin is on general grounds very unlikely; the body would become actively immune, and if it did not it should be easy enough to make it passively immune by injecting *welchii* antitoxin; this has no effect on the course of the disease. But if *B. welchii* and streptococci do not cause the disease directly by their hæmolysins, it does not follow that they play no rôle in its pathogenesis. The absence of acid from the stomach is a grave abnormality and is obviously likely to upset the bacteriology of the alimentary tract, at any rate in its upper part. An abnormal abundance of organisms has been described by a number of observers, and the whole subject is reviewed in a comprehensive way in the current number of the *Journal of Pathology and Bacteriology*, by Dr. Stanley Davidson, of Edinburgh, who has elaborately studied 41 cases of pernicious anæmia along with normal controls and examples of other diseases, examining the fæces and the gastric and duodenal contents; these two last cannot, he says, be separated, since the patulous pylorus of pernicious anæmia leaves the stomach and duodenum in free communication. His results are, briefly, that in pernicious anæmia there is a great numerical increase in *B. coli*, streptococci, and *B. welchii*, both in the stomach and in the stools. These microbes are normal inhabitants of the human alimentary tract, and a careful investigation of their varieties failed to show any qualitative difference between those found in healthy persons and those from pernicious anæmia. He concludes that there is no evidence that any individual type of organism is specifically related to pernicious anæmia. At the same time, he attributes great ætiological importance to the quantitative increase of bacteria, especially at levels in the small intestine which in normal persons are relatively free from bacteria. It may be supposed that these act by producing, directly or indirectly, substances which, passing by the portal circulation, impede the action of the liver. The gastro-duodenal sepsis runs parallel with the achlorhydria, and both continue unaltered after cure by liver. On this view pernicious anæmia is a pathological but not an ætiological entity. The changes described in the flora of the alimentary tract are not quite invariably present, and other factors may less commonly play an important part. Dr. Davidson mentions a hereditary or constitutional element in the disease, but the evidence for this is rather nebulous.

MEDICAL HISTORY STATEMENTS.

A RECENT paragraph in the *Solicitors Journal* draws attention to some observations of the county court judge at Birmingham upon the practice of medical witnesses. In workmen's compensation and other cases it is often necessary that the medical practitioner should ascertain the patient's medical history before diagnosis. But the statement which the patient gives may be closely connected with the very facts which are in dispute. In the Birmingham case apparently the plaintiff's representative suggested that the medical witness had exceeded his professional duties in obtaining such a statement. On the other hand, on behalf of the defendant it was stated that the statement was obtained by the medical witness in the presence of the patient's own doctor and was written down in the presence of both. His honour Judge Ruegg, K.C., observed that nothing unusual had been done, but that it was becoming a habit with doctors to take particulars of this kind, and then to come into court and give evidence of the contents of the statement. Upon this position two comments seem proper. In the first place it is always the duty of a medical witness to distinguish between facts which are within his own direct knowledge and matters of which he has merely been told. This distinction is notoriously of great significance in the process of certifying a patient under the Lunacy Act. The second comment is that which the county court judge himself made. He thought it objectionable that doctors should obtain statements in the way mentioned, because, if a patient knew that statements were to be obtained in that way, he would hesitate to go to a doctor. Subject to these two comments it is clear that a medical witness's evidence may be useless, unless he has been made aware of the patient's medical history, and the witness is entitled to state how far the patient's condition is consistent with, or could be explained by, that history. It does not appear that an experienced county court judge could ever be misled by medical evidence properly so obtained and tendered.

SCHOOL MEDICAL OFFICERS AND THE NOTIFICATION OF MENTAL DEFECT.

THE passing of the Mental Deficiency Act, 1927, has made it necessary for the Board of Education to revise their regulations governing the notification of children and the draft of the new regulations has recently been published. These will come into force on Oct. 1st, 1928. They are decidedly shorter and simpler than the old ones, and in addition to containing certain minor alterations consequent on the changes in the Act, they make an alteration which should be welcome to local education authorities and their medical officers. The Act requires, in the case of defective children of 7 years and upwards; who are incapable by reason of mental defect of receiving benefit or further benefit in special schools or classes, or who cannot be instructed in a special school or class without detriment to the interests of the other children, that their names and addresses shall be notified by the local education authority to the local mental deficiency authority, who will then be responsible for them. Under the old regulations, if the child whom it was proposed to notify was not an idiot, imbecile, or moral imbecile, the Board of Education required that their sanction should be obtained before such notification was made. Under the new regulation this has been waived, and cases in future can be notified on the certificate of the school medical officer without reference to the Board. There is a provision that in the case of the local education authority being in doubt regarding any child so certified, they may refer the matter to the Board before discharging their statutory duty of notification, and such reference to the Board is compulsory in the case of blind or deaf children coming under Section 69 of the Education Act, 1921. It may happen that a child is certified by the medical officer as not being incapable of receiving benefit from instruction in a special class or school, but is nevertheless considered to be in need of supervision, guardianship, or institutional care. In this event the case is to be referred to the Board, and if the Board certify that there are special circumstances which render it desirable for the child to be dealt with in this way, it then becomes the duty of the local education authority to notify the case to the local mental deficiency authority. In the case of children about to be discharged from special schools on or before attaining the age of 16 years, the local education authority may still, as previously, decide as to whether notification should be made without reference to the Board. We think that the alterations which have been made will tend to simplify administration, and they are doubtless inspired by an increased confidence on the part of the Board in the efficiency of school medical officers and local education authorities.

PHARMACY AND BIOCHEMICAL DISCOVERY.

ADDRESSING the British Pharmaceutical Conference at Cheltenham on July 24th, the chairman, Mr. R. R. Bennett, B.Sc., F.I.C., selected certain aspects of biochemistry of importance to those engaged in the practice of pharmacy, dealing in succession with the practical applications of the study of hormones and vitamins. More than ever before the pharmacist, he said, is dealing with remedies which can only be assayed and standardised by biological methods, a fact which was bringing into prominence the increasing work carried out at the Pharmaceutical Society's pharmacological laboratories. The General Medical Council had been criticised for its failure to introduce biological methods of standardisation into the current British Pharmacopœia, but, said Mr. Bennett, the Council should not be blamed for that; at the date of its issue the Council could not have prescribed biological tests as there were no official standards for such tests, nor had the Council then any power to enforce such standards in the absence of a laboratory where tests could be made. It was only the coming into force in August, 1927, of the Therapeutic Substances Act of 1925 which had brought into being a Joint Committee charged with the duty of prescribing standards, tests, and units of standardisation for therapeutic substances, the purity and potency of which could not be adequately tested by chemical means. Standards had now been defined for a number of such substances, laboratories had been appointed to prepare and keep the standards, and machinery for controlling their application had been created. The Pharmacopœia Commission which would soon come into existence would, he said, accordingly be able to include in the next edition of the Pharmacopœia any therapeutic substance for which a standard of reference had been defined by the Joint Committee, and to introduce a biological method for standardising any substance for which a standard had been set up. Mr. Bennett congratulated the Pharmaceutical Society on its readiness to adapt itself to these fundamental changes, and concluded with the remark that the future of pharmacy will depend upon the continued cultivation of the scientific habit of mind and upon the power of confronting new conditions and new difficulties with systematic knowledge and perfected technique.

ETHYL PETROL.

THE internal combustion engine has its marked likes and dislikes, and, last autumn, the first consignment reached this country of a kind of fuel which had been found in America to abolish a tiresome form of engine trouble; but this ethyl gasoline, as it was called, contained a small proportion of lead tetra-ethyl in the manufacture of which distressing cases of lead poisoning were known to have occurred. The question arose whether the consumer might not also run some risk from its use, and a discussion in the House of Lords last February elicited the statements that Sir William Pope regarded lead tetra-ethyl as a poison likely to be absorbed through skin abrasions and by the lungs, and that Prof. H. B. Baker believed it might reach the body through the unabraded skin. As a result of this discussion the Minister of Health agreed to appoint a Departmental Committee to inquire into the possible dangers to health resulting from the use of motor spirit of this kind. This Committee,[1] which included distinguished chemists, toxicologists, and medical administrators, has now issued an interim report,[2] the message of which may be stated at once to be: "there is no evidence to show that the use of ethyl petrol as a motor fuel involves more dangers to health than the use of ordinary petrol." This favourable report was not unexpected in view of such evidence as is presented in the report[3] by Dr. Alice Hamilton, of Boston, to the International Labour Office. From this report it was already clear that scrupulous care has practically eliminated risk from the manufacture of tetra-ethyl lead and also from the process of blending it with petrol. Moreover, the workers so employed can be carefully supervised and fully protected. In regard to the chauffeur and the garage man who fills petrol into cars, a committee of experts issued in 1926 a considered report based on experimental work. No definite signs of lead absorption were detected after exposures of two years, and no good grounds were found for prohibiting the use of ethyl petrol as a motor fuel, provided that its distribution and use were controlled by regulations. Evidence, however, was forthcoming that, quite apart from the use of lead in petrol, lead dust does accumulate wherever motors are garaged, and that whether it originates from paint, from rubber, or from accumulators the risk of poisoning seems comparable to that which might arise from ethyl petrol. The risk from lead, however, is regarded as definitely less than that from carbon monoxide, which nowadays necessitates free ventilation of garages and motor-sheds.

The Departmental Committee's report brings Dr. Hamilton's monograph up to date and contains the evidence of Dr. J. P. Leake, of the United States Public Health Service, who assured the Committee that although careful search had been made for possible injury to health from the use of ethyl petrol, no instance of injury had come to light. It is true that there is no compulsory notification of industrial lead poisoning in the U.S.A., but Dr. Leake's inquiry extended over private sources, press-cutting bureaux, and the health authorities of each separate State, and in view of the publicity which has been drawn to this fuel it is hardly likely that any cases of poisoning should have escaped notice. In regard to the risk of inhaling lead from ethyl petrol, Sir Robert Robertson was able to assure the Committee that the first half of petrol evaporated from the mixture is entirely free from lead tetra-ethyl. The risk to health from spillage, although unproved, is regarded as a possibility not to be ruled out, and is to be the subject of further experiment. Absorption through the skin may not be as important as was supposed, for it has been shown that a monkey may be anointed 760 times with ethyl petrol, at intervals of about a day, without more than the merest trace of lead being found in its tissues after death. The Committee has been especially impressed by the reassuring fact that garage workers in the U.S.A. who have been handling ethyl petrol continuously for four to five years show no signs of lead poisoning. Although satisfied on this point the Committee emphasises the warning that ethyl petrol should be used only as a motor fuel and not for such purposes as cooking or cleaning. Sales in this country are, in fact, governed by regulations which require the dyeing of the substance red as an additional check against its use otherwise than as motor fuel, the labelling of cans and pumps, and the issue of notices to the public. The Departmental Committee has thus reported definitely on the main point at issue, although, as has been said, further investigations are to be made on certain points. In the meantime, the city of New York has just rescinded its prohibition on the sale of ethyl petrol within its borders.

THE M.A.B. ANNUAL REPORT.

THE Metropolitan Asylums Board has just published its annual report[1] for the year 1927–28, being the thirtieth year of issue. It is the familiar orange paper-covered volume of 350 pages, containing first an account in 75 pages of the Board's multifarious activities intended for the enlightenment of the public, then a number of elaborate financial and other tables, and, thirdly, a series of monographs on one aspect or another of the clinical work done under the auspices of the Board. For those who have the ingenuity and patience to find their way about this report, it is a veritable mine of information. There may still be readers who need to be reminded of the enormous scope of the Board's activities, dealing as it does with the reception and care of various classes of sick and infirm from all the unions and parishes in London. The number of occupied beds in the various institutions of the Board on the last day of the year under review was 20,746, and the total accommodation includes 8444 beds for fevers (excluding 60 for ophthalmia neonatorum and 52 for venereal diseases), 2168 beds for tuberculosis, 2006 beds in children's institutions, 9387 beds in mental hospitals (not including 355 for sane epileptics), and, finally, 734 beds in the training ship *Exmouth*, and 828 beds in casualty wards for the poor. The total annual expenditure was round about £2,350,000, allotted to the four main groups—feeble-minded, fevers, tuberculosis, and children—in the proportions roughly of 63 : 96 : 26 : 25. During the year the fever accommodation has been revised and reallotted to conform with the standard laid down by the Minister of Health—viz., 1872 cubic feet, 144 square feet, and 12 linear feet per bed, without substantial diminution in the number of beds. In these hospitals a salutory change of policy resulted in the allocation of 1581 beds to measles at the beginning of April last. Although the daily average for diphtheria during the six winter months was as high as 2483, not many scarlet fever patients were displaced, owing to the use of the Joyce Green Hospital at Dartford as a safety-valve. The concentration of cases of puerperal fever in two of the infectious hospitals, one on either side of the river, has facilitated a research by Mr. J. M. Wyatt, the obstetric consultant, into the method of infection in puerperal women; in each case, when a patient is sent in, a swab is taken by the accoucheur from the throat of the nurse or midwife in attendance on the woman. At the Western Hospital a small number of beds has been allocated, as before, to cases of poliomyelitis in the acute stage, under the supervision of Mr. George Perkins. At the North-Western Hospital a clinic was opened last June for the treatment by radium of cancer of the uterus under the supervision of Mr. Comyns Berkeley; the allotment of eight beds will suffice for the full use of two sets of radium applicators. The experiment of assembling cases of encephalitis lethargica at the Northern Convalescent Hospital, Winchmore Hill, has been continued, admission of extra-metropolitan cases having been sanctioned in order fully to utilise the allotted beds. This experimental unit, as Dr. G. A. Borthwick frankly admits, has not been productive of curative results, although it has proved valuable as an observation station, and on this ground the Board has approved its continuance. Artificial sunlight treatment has now been installed at four hospitals, two on each side of the Thames. Long Reach Hospital being under reconstruction, in May last cases of small-pox overflowed from the temporary accommodation loaned by the Willesden U.D.C. at Kingsbury, into the large reserve hospital at Joyce Green. The type of small-pox case in London now approximates closely to that which has prevailed for several years in the northern counties. In the first half of the present year 172 cases were admitted from 17 different metropolitan boroughs. During the year 437 students (of whom 79 were women) attended courses of instruction at the Board's fever hospitals. At the mental hospitals a revised dietary came into force in June, admitting of the use of fresh fruit, when obtainable, on two days a week, while a canteen for the use of patients has been established at Darenth Training Colony. A difficult situation is arising from the steady increase in the number of young able-bodied men seeking admission to casualty wards, and the Board proposes to reinstate the breaking of stone by hand as a deterrent task. No more has here been attempted than a brief outline of the Board's activities; we shall have occasion to return to some of the clinical reports.

CONTRIBUTORS to the Ferrier Memorial Fund met on July 18th under the chairmanship of Sir Charles Sherrington, and resolved to invite the Royal Society to accept the sum of £1000 in trust to found a David Ferrier Memorial Lecture. The balance of the fund will be applied as seems most suitable when the total contributions are known. The Fund is to be closed on Sept. 30th.

EPSOM COLLEGE.—Founders' Day was observed at Epsom College on Saturday last, July 28th, when the celebration included service in chapel, distribution of prizes, and a garden party on the College playing-fields, where many parents and supporters of the College were spectators of a well fought-out cricket match between the College and the old boys. After service in chapel, and a luncheon-party at which the Council of the College acted as hosts, an adjournment was made to the big school-room to hear the headmaster's report, after which the prizes were distributed by Lord Riddell. The headmaster, Mr. Arnold Powell, was able to point to a year of successful work and successful play, the number of leaving certificates obtained being large, while the successes recorded in scholarship competitions and public examinations were numerous. Further, during the year the old Epsomians had, he said, given a good account of themselves, and this was indicated by tripos lists at Oxford, Cambridge, and London Universities, and by the pass-lists of various corporations and medical schools, the Law Society, and the Institute of Actuaries. Lord Riddell then distributed the prizes and delivered a short address in which he interested and amused the audience by a character sketch of Hippocrates, whom he held up for the imitation of youth as a fine example of independent thinking, high purpose, and power of mental concentration. During the afternoon the band of the 1st Battalion of the King's Own played appropriate selections, while in the evening a choral performance of *Iolanthe* was given by the College Musical Society. The organisation of the celebrations was excellent.

education authority to the local mental deficiency authority, who will then be responsible for them. Under the old regulations, if the child whom it was proposed to notify was not an idiot, imbecile, or moral imbecile, the Board of Education required that their sanction should be obtained before such notification was made. Under the new regulation this has been waived, and cases in future can be notified on the certificate of the school medical officer without reference to the Board. There is a provision that in the case of the local education authority being in doubt regarding any child so certified, they may refer the matter to the Board before discharging their statutory duty of notification, and such reference to the Board is compulsory in the case of blind or deaf children coming under Section 69 of the Education Act, 1921. It may happen that a child is certified by the medical officer as not being incapable of receiving benefit from instruction in a special class or school, but is nevertheless considered to be in need of supervision, guardianship, or institutional care. In this event the case is to be referred to the Board, and if the Board certify that there are special circumstances which render it desirable for the child to be dealt with in this way, it then becomes the duty of the local education authority to notify the case to the local mental deficiency authority. In the case of children about to be discharged from special schools on or before attaining the age of 16 years, the local education authority may still, as previously, decide as to whether notification should be made without reference to the Board. We think that the alterations which have been made will tend to simplify administration, and they are doubtless inspired by an increased confidence on the part of the Board in the efficiency of school medical officers and local education authorities.

PHARMACY AND BIOCHEMICAL DISCOVERY.

ADDRESSING the British Pharmaceutical Conference at Cheltenham on July 24th, the chairman, Mr. R. R. Bennett, B.Sc., F.I.C., selected certain aspects of biochemistry of importance to those engaged in the practice of pharmacy, dealing in succession with the practical applications of the study of hormones and vitamins. More than ever before the pharmacist, he said, is dealing with remedies which can only be assayed and standardised by biological methods, a fact which was bringing into prominence the increasing work carried out at the Pharmaceutical Society's pharmacological laboratories. The General Medical Council had been criticised for its failure to introduce biological methods of standardisation into the current British Pharmacopœia, but, said Mr. Bennett, the Council should not be blamed for that; at the date of its issue the Council could not have prescribed biological tests as there were no official standards for such tests, nor had the Council then any power to enforce such standards in the absence of a laboratory where tests could be made. It was only the coming into force in August, 1927, of the Therapeutic Substances Act of 1925 which had brought into being a Joint Committee charged with the duty of prescribing standards, tests, and units of standardisation for therapeutic substances, the purity and potency of which could not be adequately tested by chemical means. Standards had now been defined for a number of such substances, laboratories had been appointed to prepare and keep the standards, and machinery for controlling their application had been created. The Pharmacopœia Commission which would soon come into existence would, he said, accordingly be able to include in the next edition of the Pharmacopœia any therapeutic substance for which a standard of reference had been defined by the Joint Committee, and to introduce a biological method for standardising any substance for which a standard had been set up. Mr. Bennett congratulated the Pharmaceutical Society on its readiness to adapt itself to these fundamental changes, and concluded with the remark that the future of pharmacy will depend upon the continued cultivation of the scientific habit of mind and upon the power of confronting new conditions and new difficulties with systematic knowledge and perfected technique.

ETHYL PETROL.

THE internal combustion engine has its marked likes and dislikes, and, last autumn, the first consignment reached this country of a kind of fuel which had been found in America to abolish a tiresome form of engine trouble; but this ethyl gasoline, as it was called, contained a small proportion of lead tetra-ethyl in the manufacture of which distressing cases of lead poisoning were known to have occurred. The question arose whether the consumer might not also run some risk from its use, and a discussion in the House of Lords last February elicited the statements that Sir William Pope regarded lead tetra-ethyl as a poison likely to be absorbed through skin abrasions and by the lungs, and that Prof. H. B. Baker believed it might reach the body through the unabraded skin. As a result of this discussion the Minister of Health agreed to appoint a Departmental Committee to inquire into the possible dangers to health resulting from the use of motor spirit of this kind. This Committee,[1] which included distinguished chemists, toxicologists, and medical administrators, has now issued an interim report,[2] the message of which may be stated at once to be: "there is no evidence to show that the use of ethyl petrol as a motor fuel involves more dangers to health than the use of ordinary petrol." This favourable report was not unexpected in view of such evidence as is presented in the report[3] by Dr. Alice Hamilton, of Boston, to the International Labour Office. From this report it was already clear that scrupulous care has practically eliminated risk from the manufacture of tetra-ethyl lead and also from the process of blending it with petrol. Moreover, the workers so employed can be carefully supervised and fully protected. In regard to the chauffeur and the garage man who fills petrol into cars, a committee of experts issued in 1926 a considered report based on experimental work. No definite signs of lead absorption were detected after exposures of two years, and no good grounds were found for prohibiting the use of ethyl petrol as a motor fuel, provided that its distribution and use were controlled by regulations. Evidence, however, was forthcoming that, quite apart from the use of lead in petrol, lead dust does accumulate wherever motors are garaged, and that whether it originates from paint, from rubber, or from accumulators the risk of poisoning seems comparable to that which might arise from ethyl petrol. The risk from lead, however, is regarded as definitely less than that from carbon monoxide, which nowadays necessitates free ventilation of garages and motor-sheds.

The Departmental Committee's report brings Dr. Hamilton's monograph up to date and contains the evidence of Dr. J. P. Leake, of the United States Public Health Service, who assured the Committee that although careful search had been made for possible injury to health from the use of ethyl petrol, no instance of injury had come to light. It is true that there is no compulsory notification of industrial lead poisoning in the U.S.A., but Dr. Leake's inquiry extended over private sources, press-cutting bureaux, and the health authorities of each separate State, and in view of the publicity which has been drawn to this fuel it is hardly likely that any cases of poisoning should have escaped notice. In regard to the risk

"*An Infernal Machine.*"

The fact that England may still play some part in Irish affairs was brought home to the meeting by Dr. J. C. LOUGHRIDGE and Dr. J. R. GILLESPIE, from whose speeches it appeared that Belfast Corporation, in the course of departmental reforms, had introduced a system of "clocking in and out." To this indignity even the medical officers were asked to submit, and one of them, rather than do so, had incontinently resigned. They felt very keenly about this in Ireland, and they invited the Representative Body to say that it objected to medical officers "being required to record the time of their arrival at, or departure from, duty on a recording machine, as it is derogatory to the dignity of the profession." There was all the difference between signing one's name in a book and using an infernal machine; the second method implied disbelief in one's honour. The B.M.A. had no more loyal adherents than in Northern Ireland (statistics of membership were here quoted), and "God help us," said Dr. Gillespie, "if we can't have the help of this mighty organisation."

They got it, the motion being carried with no dissentient voice.

Public Health and Poor-law.

Several resolutions introduced by Dr. E. LEWYS-LLOYD, Chairman of the Public Health Committee, were carried without much discussion. The first laid down that all tuberculosis officers whose clinical work in areas is not subject to detailed supervision by the chief tuberculosis officer should be entitled to a minimal commencing salary of £750 per annum. The second dealt with pathological reports, and ran as follows:—

> That the work of laboratories established by public health authorities should, in the opinion of the Representative Body, neither provide for pathological examinations nor furnish reports on individual cases, except (1) in cases which directly involve questions of public health, or (2) where provision is made for such reports by statutory right, or (3) when the patient is stated by the practitioner to be unable to pay a fee; provided that in parts of the country where facilities for pathological examinations and reports are not afforded either by private practitioners (pathologists) or by the service of the local hospital, the public health laboratory may properly make examinations and furnish reports as these are required by practitioners for patients who are in a position to pay the usual professional fees.

The meeting agreed that in areas where there are cases of small-pox, and where propaganda work in favour of vaccination is not carried out by the local authority, the local division should try to stimulate the authority to do this work or else do what it can to supply the deficiency.

Another resolution, described by one representative as the "anchor of the general practitioner's freedom," made clear the Association's policy that "domiciliary attendance should, in the best interests of the patients, be provided by private practitioners in the area concerned and not by a whole-time medical officer." This was not to prejudice the position of any medical officers at present holding whole-time appointments in which domiciliary attendance was one of the duties, nor would it, of course, apply in areas where no general practitioner was willing to undertake the work on suitable terms.

The question of the combination of the duties of medical officers, poor-law medical officers, and public vaccinators was discussed in the light of probable changes in poor-law administration. Dr. H. B. BRACKENBURY, Chairman of Council, explained that the combination of these offices was now approved by the Minister of Health, and Dr. MILBANK SMITH said that when the poor-law was abolished, it must be ensured that vaccination work was not transferred to the medical officer of health. The rights of the private practitioner must be safeguarded. The meeting agreed that there was no objection in principle to the combination in one and the same whole-time appointment of (*a*) the duties of a M.O.H. and those of a poor-law institutional medical officer, or (*b*) the duties of an M.O.H. or poor-law institutional officer and those of a public vaccinator. But the application of these principles in any individual instance "must be governed by local circumstances and by the opinion of the Division or Divisions concerned."

Spa Treatment of Panel Patients.

Dr. H. G. DAIN, Chairman of the Insurance Acts Committee, introduced a scheme drawn up by the British Spa Federation for the provision of treatment for insured persons at various British spas. He said that the approved societies were not yet in a position to provide this form of additional benefit, but they might be able to do so out of their "disposable surpluses" after the next valuation. Meanwhile the Federation wished to be ready, and their scheme need cause no anxiety to the private practitioner, since all it demanded from him was the filling-up of a simple form of recommendation.

Criticisms were nevertheless raised from various points of view. Dr. A. T. JONES, for North Glamorgan and Brecknock, wanted to know exactly what was the position of private practitioners in the towns to which the cases would be sent. What was the definition of the "spa physician" by whom the cases would be treated? He wanted an assurance that the care of these patients would not be the prerogative of a few.—Dr. H. M. RAVEN (Broadstairs) thought that the fee of a guinea given to the spa physician for three weeks' treatment, exclusive of radiographic and bacteriological investigations, compared favourably with the fee of "about a shilling" which seaside practitioners got for three months' temporary residence by an insured person in their area.—Dr. L. W. BATTEN suggested that the spa physician's privileges were better defined than his duties.

Dr. E. R. FOTHERGILL, who had helped to draw up the scheme, agreed that participation in the treatment ought to be open to all those who had good credentials, and should certainly not be reserved for members of hospital staffs. Dr. DAIN cleared up the position by quoting certain criteria of a specialist—namely, that he should satisfy one or more of the following conditions:—

> 1. That he holds or has held hospital or other appointments affording special opportunities for acquiring special skill and experience of the kind required for the performance of the service to be rendered, and has had actual recent practice in performing the service to be rendered or services of a similar character; (2) that he has had special academic or post-graduate study of a subject which comprises the service to be rendered, and has had actual recent practice as aforesaid; or (3) that he is generally recognised by other practitioners in the area as having special proficiency and experience in a subject which comprises the service to be rendered.

This definition was accepted by the meeting, and Dr. JONES was assured that it did not preclude panel practitioners from being recognised as suitable persons to give treatment of the kind contemplated. Dr. E. SOLLY (Harrogate) said that there was now a very strong movement towards the provision of so-called spa treatment for insured persons, and on no account must this treatment be given by persons with no special experience.—Dr. F. G. THOMSON (Bath) explained what services the spa physician would render, and after Dr. DAIN had summed up the case in its favour, the scheme was approved with only two or three dissentients.

What is a Spa?

An entertaining discussion arose on an attempt by the Council to define spa treatment as "treatment at a place possessing a supply of natural mineral waters of reputed therapeutic value with facilities for their application. This implies the existence of suitable buildings, apparatus and trained personnel for work in bathhouses and other physiotherapeutic departments." Dr. E. WARD, for Torquay, moved that the word "mineral" should be deleted so that the definition might include sea-water, and this

BRITISH MEDICAL ASSOCIATION.

ANNUAL MEETING AT CARDIFF.

REPRESENTATIVE MEETING: JULY 21ST-24TH.

(*Continued from p. 196.*)

Lunacy Law Reform.

Dr. R. L. LANGDON-DOWN, Chairman of the Committee on Lunacy Law and Mental Disorder, introduced the Council's memorandum on the Report of the Royal Commission published in 1926. He said that the Council did not regard as satisfactory the proposal that mental patients should be classified as "voluntary" and "involuntary." The Commissioners recommended that those who entered a mental institution on their own initiative should be termed voluntary patients whilst all the others were to be placed under compulsory treatment only after medical examination and on the order of a magistrate. Thus the proposed Provisional Treatment Order, except in the case of the voluntary boarder, involved the intervention of a legal official at the outset for every patient who required institutional treatment. This was by no means desirable, as the memorandum pointed out; in fact, if the early treatment of mental disorders was to be realised, legal intervention should be limited to cases in which the patient, *though capable of volition, definitely refused and resisted* institutional treatment. There were numerous patients in whom the will was in abeyance; many of these made an early recovery, and they ought if possible to be saved from the stigma of certification. The Council thought that they should be admitted to appropriate institutions on an "authorisation for treatment" given by a relative or friend and supported by the recommendation of two practitioners. On such terms it would be possible to get relatively early treatment, whereas the Commission's plan, by continuing in this respect the formalities of the existing law, would discourage a patient's relatives from taking steps in good time. The intervention of a justice was the great deterrent to early treatment at the present time.

Dr. DAVID ROXBURGH, for Marylebone, proposed that the report be referred back for further consideration on the ground that the Council had not "taken steps to promote legislation which would protect the certifying practitioner from vexatious litigation." There was, he said, a sword hanging over the head of anyone signing a certificate of insanity, and it must somehow be removed. Sir Frederick Willis, the late Chairman of the Board of Control, had stated in the press that the Board had for ten years been making strenuous efforts to get the law of lunacy altered, but public apathy had always resulted in measures of reform being crowded out of Parliament. As a powerful body like the Board had failed in all this long time to get anything done, the only thing left to the profession was to frighten the public into taking an interest in the subject. This could be done if medical men as a body would threaten not to continue the certification of the insane, and to do this would be a public service.

Dr. Roxburgh's motion to refer the report back to the Council was lost.

Dr. TEMPLE GREY did not approve of the Commissioners' statement, quoted in the memorandum, that "insanity is, after all, only a disease, like other diseases. . . ." This was not true from the point of view of diagnosis—the point of view of the general practitioner. In cases where the judicial authority intervened to secure detention in the public interest for persons of unsound mind, that authority ought, he considered, to accept responsibility for such detention.—Dr. LANGDON-DOWN said that proposals of this kind lost sight of the other functions performed by doctors under the Lunacy Act. A magistrate could not take over a medical man's whole responsibility, since the latter would always be liable to an action for lack of care in making out the certificate. It would be wholly unsatisfactory, indeed, if the doctor were released from the duty of taking care.—To this Dr. GREY replied that absolution from the duty of care did not mean the right to be careless. He thought that a magistrate should always be called in if the patient proved resistant, and in the comparatively small proportion of cases where this happened, the law should accept the responsibility. After some further discussion this view was accepted by the meeting, which passed the following resolution, to be added as a rider to the Council's report:—

> That the Representative Body, whilst thanking the Lunacy Law and Mental Disorder Committee for their Memorandum, considers that further protection for the certifying medical practitioner is required; that is to say, that the judicial authority when it intervenes shall accept responsibility for the detention of persons of unsound mind.

Dr. W. JOHNSON SMYTH and Dr. E. K. LE FLEMING, for Bournemouth, put forward another amendment to the original motion accepting the memorandum. This ran as follows:—

> That if, under Sections 13 and 16 of the Lunacy Act, 1890, a magistrate make an order to one or two medical men as the case may be (two medical men under Section 13 and one under Section 16) to examine a person believed to be of unsound mind, it should be considered that the magistrate should be solely responsible as an instrument of the law and the doctors should have the status of a witness and enjoy the immunities of a witness.

Dr. GREY had previously pointed out that the words "status of a witness" could not be applied in the circumstances; properly speaking, no one but a witness could have the status of a witness. The Bournemouth amendment was, however, carried, after references to Section 16 had been deleted.

Conflicting Medical Evidence in the Courts.

Dr. R. G. GORDON, for Bath, drew attention to the Assize Court's decision in the case of Tyndall *v.* Alcock. Heavy damages had been given against Mr. Alcock, largely on evidence which seemed to be wise after the event, and on appeal the judge had said in so many words that if the original decision had been in the hands of himself and his colleagues, the result would no doubt have been different. As no new facts had emerged he was, however, unable to reverse the opinion of the jury. Dr. Gordon invited the Representative Body to say that it regarded the case with consternation since it "would seem to expose any surgeon who, although operating in good faith and with due precautions, failed to obtain a perfect result from his operation to be found in damages by a jury of laymen." It was, he said, impossible to expect that the jury system would be altered, but a certain amount of abuse was creeping into the practice of giving medical evidence in the law courts, and it was desirable that the question should be ventilated. Possibly a medical assessor—an "impartial person"—ought to sit with the judge to help him in the weighing of technical evidence. On behalf of Bath he proposed that the Council should consider "whether means cannot be found to ensure that expert witnesses appearing on opposite sides in a case shall not so confuse the issue by a divergent representation of facts that a lay jury cannot assess these facts at their true value."

The meeting asked Mr. O. Hempson, the Association's solicitor, to express an opinion on this proposal, and he thought that, if passed, it might well be quoted against members of the profession in cases of alleged negligence. It would always be possible for litigants to obtain the services of a certain class of medical man, and the weight of such witnesses' opinions would be increased if they could be represented as men who had courage enough to put the interests of truth before those of their profession. Mr. Hempson believed that it would be a great mistake to pass a resolution suggesting that the B.M.A. deplored medical men giving evidence against each other.

Dr. Gordon consented to withdraw his motion.

impossible to please both parties.—Dr. **Temple Grey** urged postponement. He did not like the suggestion that the central consultative council should be set up by the Ministry of Health.—Mr. **H. S. Souttar**, however, said that if the Association's decision was to be of any value it must be sent to the Minister at once. It was surely obvious that there must be some consultative body to coördinate hospital work. The object of having base hospitals was to save waste of time and energy; they were not going to take "good" cases, but were going to set an example of what could be done, and were going to help others in every possible way. Whilst it was the duty of public hospitals to take all and sundry patients, it was the duty of voluntary hospitals to supply the highest possible level of medical service, to provide education for medical men, and so far as possible to assist the public services.

Dr. **C. E. S. Flemming** saw no reason to fear that the State would want to control voluntary hospitals. Even State aid would not necessarily mean State interference.—Sir **Richard Luce**, M.P., said that coördination would be impossible without the intervention of some outside body, representing the interests of all concerned. Cottage hospitals, fever hospitals, and the rest would look to the base hospitals as educational centres, and they would be a very important element in post-graduate work.—Dr. **Fothergill** was much more frightened of State hospitals than of voluntary hospitals, the majority of which in this country were staffed by general practitioners.—Dr. **R. C. Buist**, speaking as a member of the Voluntary Hospitals Commission, said he had signed with a heavy heart that section of the Commission's report which dealt with financial assistance of the voluntary hospitals from mass contributions. When the poor-law hospital became municipal and lost its stigma, it would inevitably come into competition with the voluntary hospital, and if its service was adequate it would win sooner or later. People who provided treatment for themselves by paying rates would eventually drop out of contributory schemes.—Dr. **A. B. Murray** pointed out that already very few hospitals were truly voluntary; their work on venereal diseases, child welfare, ophthalmia neonatorum, and in other directions was State-aided. Whereas in big hospitals the voluntary staffs, in giving their services, were only casting bread upon the waters, practitioners who joined the staffs of small country hospitals did their work for nothing and got no indirect return. Much of this work should be paid for—a suggestion which had found no place in the memorandum.

While summing up in favour of referring back the memorandum to the Council, Dr. **Masterman** said that in his Division there were 2400 beds belonging to public authorities, and no voluntary hospitals. Every practitioner was welcome to come in, examine, and talk over his case. He visualised, in the future, an annexe in State hospitals where practitioners could definitely undertake the treatment of their own patients.

The amendment being lost by a large majority, the meeting approved the Council's memorandum. Further discussion took place on the criteria for practitioners treating private patients in private wards or nursing homes attached to hospitals, but this question was referred for further consideration

Other Subjects Discussed.

The following motion by Edinburgh and Leith was approved without discussion:—

(1) That in the interest of the public health the British Medical Association support any measures which may be taken so to alter or amend existing legislation as to give greater power to local authorities to suppress unnecessary noise which is disturbing to the lieges; and (2) that any noise from 11 P.M. to 6 A.M. which is capable of being prevented or mitigated and which is dangerous or injurious to health, shall be a nuisance within the meaning of the Public Health Acts.

A resolution passed in 1926, saying that in accident cases treated at a voluntary hospital, where medical attendance is covered directly or indirectly by insurance, "the hospital authorities should recover from the insurance company the full cost of maintenance and treatment," was amended by deletion of the words "from the insurance company."—Buckinghamshire carried a motion asking the Council to consider whether some arrangement could be made for payment for the emergency services rendered by doctors to patients meeting with accidents on the roads.

In introducing the report of the Naval and Military Committee, Dr. **F. W. Goodbody**, the chairman, advised that careful inquiries should be made at the present time before advising medical men to enter the Indian Medical Service.

Dr. **C. L. Leipoldt**, Secretary of the British Medical Association in South Africa, referred to the need for improving post-graduate education in England. Practitioners from the Dominions regarded themselves not as students but as the equals of any practitioner in this country. They therefore did not appreciate the instructive methods of specialists at the big teaching hospitals in this country.

At the end of the meeting a cordial vote of thanks was passed to Dr. Hawthorne for presiding, and to other officials who had worked for the comfort and convenience of the meeting.

THE ANNUAL MEETING.

At the annual meeting at the City Hall on July 24th the outgoing President, Sir Robert Philip, handed the insignia of office to his successor, Sir Ewen Maclean. The President-elect, Prof. A. H. Burgess, was introduced to the assembly. At the adjourned annual meeting, held at the New Theatre on the evening of the same day, the new President delivered the address published in our last issue. The Sir Charles Hastings Clinical Prize was awarded to Dr. Ambrose Owen, the Stewart Prize to Sir Malcolm Watson, and the Katherine Bishop Harman Prize to Dr. Ronald Hare.

THE RELIGIOUS SERVICE.

At the official church service, held at St. John's Church on July 24th, the sermon was preached by the Rev. Garfield Williams, M.B., honorary Canon of St. Albans, who spoke on the character of St. Luke. Even yet, he said, the Church had not realised the importance of what might be described as the extra-professional activities of that travelling physician of the first century. He was the greatest biographer of our Lord, so far as pure biography was concerned; he was the first and greatest of Church historians, and he was the companion and guardian of Paul the missionary. He had the practical mind of the physician, and he thought out the ways and means whereby the visions of his companion Paul might be carried out into action. One side of his character to which the preacher drew attention was his interest in persons—in personal details, at all events those which were important. That was true of the physician always. He did not treat diseases, in spite of what the public might suppose; he treated persons.

THE ANNUAL DINNER.

More than 500 people attended the annual dinner of the Association, held at the City Hall on July 26th, when Sir Ewen Maclean presided, and the guests included the Lord Mayor and Lady Mayoress of Cardiff, the Marquis and Marchioness of Bute, the Archbishop of Cardiff, Dr. Franklin Martin (director-general of the American College of Surgeons), and Sir George Syme (president of the Federal Committee of the B.M.A. in Australia).

Proposing the health of the City of Cardiff, Mr. R. G. Hogarth said that, like many other visitors, he had imagined Cardiff as a city of smoke and ugliness; he found it endowed with civic buildings unrivalled in many a European capital. It was interesting to think of all these beautiful and proposal was warmly seconded by Dr. JOHNSON SMYTH, of Bournemouth, who also drew attention to the excellent facilities provided for the treatment of rheumatism at certain seaside resorts.—Dr. BRACKENBURY protested vigorously against this tampering with the definition. It would mean, he said, that nearly every town and village round the coasts of the Empire could claim to be a spa—and most of those inland as well. But the claims of seaside watering-places had made a strong impression. and Torquay's amendment was carried. A proposal by Mr. BISHOP HARMAN to destroy its general effect by inserting the word "approved" before "water" was rejected with ignominy, but Dr. BRACKENBURY eventually managed to persuade the representatives that the amended version was unsatisfactory, and the definition was referred back to the Council for further consideration.

Contract Rate for Juvenile Oddfellows.

A lively debate arose on the Council's decision that a standard rate of 8*s.* 8*d.* per head per year, including drugs, was acceptable for medical attendance on juvenile members of the Manchester Unity of the Independent Order of Oddfellows. This body has found its numbers diminishing through insufficient entries into the juvenile lodges. Failure of recruiting has been due to medical benefit being no longer given in many areas because it costs too much, and the Manchester Oddfellows have approached the B.M.A. to see whether such benefit cannot be provided at an economic rate. The policy of the Association has been that the same fee should be paid as under the National Health Insurance Acts—namely, 9*s.* plus 2*s.* 3*d.* or thereabouts, including medicine—but this policy, Dr. BONE reported, has been more honoured in the breach than the observance. There were few areas, he said, where anything like a capitation fee of 8*s.* 8*d.* had been obtained for dependants of the classes insured under the Health Insurance Acts, and the Council thought that it was a fair fee for the particular work to be done. There were in the Society 151,000 juvenile members, and the capitation fee at present being paid on their behalf was between 6*s.* and 7*s.* The profession would gain some £20,000 by a uniform rate of 8*s.* 8*d.*, and in comparing this rate with fees received in the public medical service it must be remembered that there would be no deduction for the costs of collection and expenses generally, and that the service given would be relatively restricted as the children were under 16 years of age and needed less attention. Dr. BRACKENBURY said that the advantage of getting rid of records, of the need of certification, and of the disciplinary machinery was more than equivalent to any drug fees the practitioner would get if he had to provide the patients with medicine. He thought that 8*s.* 8*d.* was at least equal to the fee now being received under the Insurance Act.

This view was challenged by several representatives, whilst others maintained that 13*s.* per head per annum could be secured in many areas. Some pointed out that children should receive more and not less attention than adults. Dr. LEWIS LILLEY, for Leicester and Rutland, moved that the standard rate be approved "always provided that in any area in which a higher rate at present is paid this rate shall be allowed to stand, due regard being given to the special conditions and scope of service rendered in such area." But this amendment was lost, and the meeting finally approved the Council's resolution by a majority of 81 to 63. This resolution not only agreed to the standard rate of 8*s.* 8*d.*, but also authorised the Council to approve a slightly lower rate in areas where, owing to economic conditions, the standard rate was not feasible. It laid down "that it be an essential part of this arrangement that there must be free choice of doctor by patient and of patient by doctor."

As the vote did not show the necessary two-thirds majority in favour of the resolution, it will not become part of the policy of the Association.

Coördination of Hospitals.

The Council having approved a memorandum for presentation to the Minister of Health, this was introduced to the Representative Body by Mr. MCADAM ECCLES, Chairman of the Hospitals Committee. It outlines a scheme based on the assumption that poor-law hospitals will shortly come under the control of county and borough councils. The first step in coördinating their work with that of the voluntary hospitals must, in the Council's opinion, be the establishment of a central advisory authority appointed by the Ministry of Health. This "central consultative hospitals council" should map out the country into areas—each served by an "area coördinating hospital committee"—containing both voluntary and municipal hospitals. These would again be subdivided and, as suggested in the Interim Report of the Consultative Council on Medical and Allied Services, 1920 (the Dawson Report), all the hospitals in a given district would be grouped round a central or base hospital—generally one of the bigger voluntary hospitals. This would be expected to set the standard of hospital practice and be the chief centre of education and research. As the "area coördinating hospital committees" would generally cover districts too large for administrative control, each group of hospitals would work under the direct advice—and in some respects administration—of a group hospital committee. A public hospital, when not itself the central or base hospital, should develop in coöperation and not in competition with the voluntary hospital. The responsibility for treatment in public hospitals could be undertaken by a visiting medical staff (on a part-time basis) with the assistance of a resident medical staff; but practitioners treating patients for whom the Government or local authorities are responsible, should receive either an honorarium or a fixed salary for definite services and responsibility.

A proposal to refer the memorandum back to the Council for further consideration was made from different points of view by Dr. E. W. G. Masterman, for Camberwell, and by Dr. Graham Little, M.P.

Dr. MASTERMAN said that this was a consultants' scheme. In the opinion of all the medical superintendents of poor-law institutions it was "impossible" and it would wreck all attempts at coöperation and helpfulness. He was all in favour of the voluntary system, but if the voluntary hospitals kept out of the State service they could not expect quite the same consideration as if they were in it. In the scheme, the base hospital should logically be the State hospital, because this was obliged to take any patient requiring treatment, whereas the voluntary hospitals, especially those with students, were obliged to select their cases. He did not believe, however, that it was wise to put any hospital in a primary or superior position in a district. Nor could he approve the suggestion that in public hospitals responsibility for treatment should be taken by the visiting staff. In public health hospitals at the present time there was a whole-time regular staff and consultants were only called in when necessary.

Dr. GRAHAM LITTLE pointed out that the Dawson Report had been published eight years ago when the situation of the voluntary hospitals was desperate. Now 75 per cent. of those in the provinces, and 60 per cent. of those in London, had balances at their banks. It was dangerous to give this opening to the Ministry of Health for controlling the voluntary hospitals, and it would be very regrettable if the policy of the Association were to weaken the voluntary system.

Dr. M. W. RENTON (Stratford) complained that the threshold of the voluntary hospitals was too often closed to general practitioners. There was a mistaken idea that the whole of the work should be done by consultants.—Mr. BISHOP HARMAN contrasted the views of Dr. Masterman and Dr. Little in their opposition to the scheme. It would be a definite lesion of the myocardium—178 presented fibrosis, 12 fibrosis and fatty change, and 48 fatty change alone. Atheroma was the most frequent lesion and caused fibrosis in 51·2 per cent. of cases. Many of the cases illustrated the remarkable adaptability of the anastomotic channels under favourable conditions. From this study, in addition to general information regarding frequency and effects of lesions, three points emerged: (1) severe coronary narrowing might be present without obvious lesion in the myocardium; (2) old-standing severe arterial lesions and actual occlusion with fibrosis might occur with no clinical history pointing to it; (3) patients might die with symptoms suggesting coronary artery occlusion and no such lesion be found. There was no diagnostic symptomatology which would cover all cases of coronary disease. When the blockage was abrupt certain features were present. Hamman divided cases into six classes: (1) sudden death; (2) death in a few hours; (3) continued myocardial insufficiency with death in weeks or months; (4) recovery after grave symptoms; (5) cases that were not grave but recognisable; (6) mild or uncertain cases. He would leave symptomatology to other speakers. The prognosis was grave, but owing to difficulties in diagnosing mild cases, the proportion of recoveries could not be stated. In treatment they must distinguish between treatment of the actual disease and treatment of a complication, such as thrombosis, arising in the course of that disease. In thrombosis the first indication was to relieve the pain. Morphine was required, often in large doses. Digitalis was sometimes of benefit. He himself had been impressed with the value of glucose in strengthening the heart, but had not been able to follow a sufficiently large series of cases to speak dogmatically. He gave half a pound daily. Treatment of actual disease of the coronary arteries resolved itself into prevention of such conditions as atheroma and arterio-sclerosis. This could not be efficient until their ætiology was better known.

Ischæmia and Infarction.

Dr. **Carey F. Coombs** (Bristol) based his remarks on cases seen as in-patients. He defined two chief coronary syndromes, ischæmia and infarction. In ischæmia there was substernal pain, excited by exertion and relieved by rest. In infarction the substernal pain was continuous. These groups were clearly defined, although it was difficult to draw a line between them, since a case of ischæmia might pass over into one of thrombosis. The age-incidence of ischæmia and infarction corresponded fairly closely but the highest peak of the curve for ischæmia occurred about a decade earlier than that for infarction. The reason for this was that ischæmia was generally due to syphilis, which caused nipping of the orifice of the coronary arteries but rarely led to infarction, whereas degenerative conditions, especially atheroma, caused destruction of the intima and infarction. With regard to sex-incidence, males preponderated to the extent of 71 per cent. in ischæmia and 82 per cent. in infarction. Most of the females in the ischæmic group had high arterial tension, but this was not so for the males. The effect of heredity could not be statistically proved, as it was difficult to get accurate family histories. The patients died at an advanced age (60–70), so that the family history had been forgotten. Nevertheless, there was a decided family incidence; several examples were quoted.

The ætiology of coronary disease was graphically shown. Rheumatism and ulcerative endocarditis seldom produced gross lesions, for although much damage to vessels was found microscopically, there was, as a rule, no interference with the blood-supply. Very interesting were the infective group of cases, of which the speaker had seen several examples occurring about the age of 40 and often associated with phlebitis. Most of the cases were of the degenerative type and arose from circumstances over which they had little or no control. With regard to treatment, he had found caffeine and diuretin of value in patients who suffered from cardiac pain on slight provocation.

Dr. **Ivor J. Davies** (Cardiff) emphasised the importance of looking for arterio-sclerosis or atheroma in clinical examination of patients. Burns, in 1809, had compared the diseased heart to a limb round which a moderately tight ligature had been tied. Ordinary work could be carried out, but further exertion produced the symptoms of intermittent claudication. Intermittent claudication was the probable cause of the pain of coronary disease. True cardiac pain did not occur in valvular disease unless decompensation was also present. The character of the pain was important. It tended to be epigastric in coronary thrombosis, hence the liability to confusion with abdominal disease. Angor animi was pathognomonic of coronary disease and emotional stress was often an exciting cause of the pain. The speaker then gave an account of the symptoms and physical signs of thrombosis, laying special stress on restlessness, especially if it occurred in a patient already suffering from heart disease.

Diagnosis and Prognosis.

Dr. **A. G. Gibson** (Oxford) dealt with diagnosis and prognosis. Coronary disease should be suspected in cases of: (1) serious pain in the chest; (2) acute cardiac failure with fainting attacks; (3) acute pain in the upper abdomen with an irregular heart. It was necessary to distinguish between angina and coronary disease. In the former the pain came on during exertion and lasted for minutes, dyspnœa was absent, and the blood pressure was normal or raised. In the latter the symptoms lasted hours or days; there was vomiting, abnormal pulse-rate, low blood pressure (especially low pulse pressure), and, later, fever and leucocytosis. In some cases there was acute cardiac failure with pallor, sweating, restlessness, and entire absence of pain. Fainting attacks in persons over 40 should be regarded with grave suspicion. The blood pressure, pulse-rate, and response to exertion should be watched. The distinction between coronary thrombosis and acute abdominal conditions might be difficult. If they occurred together it was better to operate, for the administration of an anæsthetic, although the risk was greater, did not present insuperable difficulties. Coronary disease might be suspected in chronic cardiac failure occurring in older people. But however careful they might be in diagnosis, there would be some cases impossible to identify during life. With regard to prognosis, figures did not help much until the different factors concerned in the condition could be separated. Patients who recovered from an attack of thrombosis might live many years even with extensive fibrosis of the heart muscle. Specimens of hearts from two such cases were shown.

Dr. **John S. Campbell** (Belfast) showed a series of X rays of hearts in which the coronary circulation had been injected with an opaque emulsion. Age changes were illustrated by a fœtal heart where the right and left ventricles received an equal blood-supply, the heart of a man of 50 showing decreased vascularity of the right ventricle, slightly tortuous arteries, and better developed anastomoses, and that of a man of 75 where these changes were much more marked. The next series dealt with anastomoses developing after coronary thrombosis. In one case of thrombosis of the right coronary and circumflex the whole of the arterial tree distal to the block had become filled with injection material through anastomoses with branches of the left coronary. Diagrams of variations in the areas supplied by the two coronaries were also shown.

Dr. **D. Evan Bedford** (London) spoke of electrocardiographic changes and described the typical curves found in coronary thrombosis. Widening of the curves, splintering or notching of the waves, and low voltage were common in coronary disease. He showed electrocardiograms taken two days and four days after coronary thrombosis. Besides the above, concordant buildings as an expression of the coal trade, now going through a time of trouble, and he trusted that the courage which had made Cardiff great would stand by her in the present difficulties. In his response the Lord Mayor said that they were all hoping that the day would come when Cardiff would be recognised as the capital of Wales, and they had already reserved a site for the National Parliament. Meanwhile Cardiff would appeal to the medical profession because it was a city without a slum. There was not one house in it that the Ministry of Health would condemn.—Dr. H. B. Brackenbury replied to the health of the British Medical Association, proposed by Sir William Seager, and Dr. C. O. Hawthorne, giving the health of the guests, coupled the toast with the names of Sir William Diamond (chairman of the Board of Management of the Cardiff Royal Infirmary) and of Sir George Syme, both of whom responded.—Dr. W. E. Thomas wittily proposed the health of the President, Sir Ewen Maclean, who was, he said, the first ex-chairman of the Representative Body to rise to this high office.—After this health had been drunk with musical honours, and Sir Ewen had replied, the proceedings ended with the National Anthem.

THE SOCIAL SIDE.

The principal building of Cardiff is the Castle, owned by the Marquis of Bute, which comprises a large Roman fort, a Norman keep, and residential buildings belonging to nearly every English architectural period. The grounds extend for several miles towards Llandaff and the part now called Cathays Park has been made over to the city as a site for national and municipal buildings. These include the Law Courts, the County Hall, the Technical College, the Welsh National Museum, the University College of South Wales and Monmouthshire, and the City Hall. In the centre lies the National War Memorial, and the whole group of buildings, constructed in Portland stone and separated by open spaces and wide avenues, is unlike anything to be seen elsewhere in this country.

The scientific sections met at University College and in the Technical College, but most of the social functions, and the Representative meeting, were held in the City Hall. On Tuesday evening the Hall was used for a reception by the President and local executive, and on this occasion a birthday present was given by the Association to the Earl of Dumfries, Lord Bute's eldest son, who was celebrating his coming-of-age. On the following evening the Hall was again used for a reception and dance, the host this time being the Lord Mayor.

On Wednesday afternoon there was a reception at the Cardiff Royal Infirmary; on Thursday Lord nd Lady Bute entertained some 6000 guests in the Castle grounds; and on Friday evening the National Museum, at an official reception, displayed its many beautiful treasures, together with a special collection llustrating the history of Welsh medicine.

On Sunday the Representative Body enjoyed an xcursion to St. Donat's Castle, where a religious ervice was held in the courtyard. Before setting out the Representatives attended at the National War Memorial, where the President-elect laid a wreath on behalf of the Association. Many expeditions to places n the locality, including the Docks and the Bargoed Colliery, were arranged during the subsequent week. The Popular Lecture was given at the New Theatre n Friday evening by Sir Berkeley Moynihan, who poke on Art in Medicine, and on Friday the honorary egree of Doctor of Laws was conferred by the University of Wales on Sir Robert Philip, Dr. H. B. Brackenbury, Dr. W. W. Chipman (Professor of Obstetrics at McGill University), Sir Thomas Lewis, Dr. Franklin Martin, and Sir George Syme.

THE ANNUAL EXHIBITION.

An account of the exhibition, which was formally pened on Tuesday by Sir Ewen Maclean, will appear a forthcoming issue of THE LANCET.

SECTION OF MEDICINE.

Sir THOMAS LEWIS, who presided at a discussion on

DISEASES OF THE CORONARY ARTERIES,

remarked that the dictum, "a man was as old as his arteries," contained a considerable element of truth, especially if it was applied to the cerebral, renal, and cardiac vessels. The coronary arteries had been the subject of discussion on several occasions in these meetings as well as elsewhere, but many problems concerning them were still wrapped in obscurity. Disease of the coronaries always interested medical men, for many notable physicians had been affected by it. John Hunter, and in modern times Sir James Mackenzie, were two out of many examples. The western counties had a peculiar interest in the condition, for the earliest and some of the most important observations on coronary vessels had originated there. 160 years ago Heberden gave the first clear description of coronary disease. Its connexion with angina pectoris was first pointed out to Edward Jenner by a surgeon living in Ross, who did a post-mortem on a case of angina and noted disease of the coronary arteries. Jenner wrote his opinion on this to Heberden in a private letter, but his views were never published, out of consideration to his friend, John Hunter. There had been great advances in recent years, in two directions especially. The first was in the study of the anatomy of the vessels of the heart and their anastomoses in heart muscle. The second was the precise study of the symptoms and signs of coronary thrombosis. This was bound to throw light on our knowledge of angina pectoris.

Dr. GEORGE A. ALLAN (Glasgow) began his opening address by defining the limits of the discussion. Speakers must beware of detracting from the value of the main subject by excursions into theories of angina pectoris. Nor must they narrow the outlook by concentrating on one aspect alone of coronary disease, such as coronary artery thrombosis. He then surveyed some of the essential features of the subject.

The association of special symptoms with occlusion of the coronary blood-supply had been recognised since 1878, but only in the last few years had a clear distinction been established between it and the more widely recognised syndrome of angina pectoris. Very important anatomical investigations had been made by Gross and his collaborators, who concluded that the heart was perhaps the richest organ in capillary and precapillary anastomoses. From the morbid anatomy point of view there were four clearly defined diseased conditions of the coronary arteries: atheroma, arterio-sclerosis, syphilis, and calcareous degenerations. These terms were often so loosely used that it was necessary to define them. Atheroma, the commonest primary lesion in the coronaries, had a patchy distribution. It was the same disease as atheroma of the aorta and had the same tendency towards ulceration and thrombosis though in a less degree. Atheroma was very irregular in its distribution in different vessels. The coronaries and other deep arteries might be affected, while the superficial arteries might give no indication of its presence. Arterio-sclerosis was a more diffuse process characterised by thickening of the media and intima. It was the same as arterio-sclerosis associated with high blood pressure and might, or might not, cause narrowing of the vessel. Syphilis, though common in the aorta, was rare in the coronaries. They were, however, liable to be occluded at their point of origin by syphilitic mesaortitis. Calcification might be superimposed on either atheroma or arterio-sclerosis, or might occur as a primary medial degeneration. The deformity it produced in association with atheroma frequently caused narrowing of the lumen with or without thrombosis.

With regard to the relative frequency of the conditions, the speaker found that out of 1000 post-mortems at the Western Infirmary, Glasgow, coronary artery disease was found in 371. Of these 238 showed

(1) when marked disparity existed between head and pelvis, hardly ever when the head was still movable above the pelvic brim; (2) without an exact knowledge of the position of the head; (3) until the cervix was completely effaced and retracted over the presenting part. It would be a counsel of perfection to forbid the application of forceps except on strict indications, but greater care and discretion in their use was a reasonable ideal.

The Importance of Antenatal Care.

Prof. James Hendry (Glasgow) pointed out that public interest in puerperal morbidity was thoroughly aroused, and that there was no doubt whatever that the doctor was held responsible. Dr. Miller had provided the records; he himself would attempt to consider to what extent more efficient antenatal care would have prevented these accidents.

In most of the cases of disproportion, contracted pelvis and not an abnormally large child had been the cause. This could nearly always have been identified in early pregnancy; skeletal irregularity was an important danger-signal. Internal examination was essential, and the form of the pelvic outlet should be noted; a sharp subpubic angle with reduced distance between the tuberosities indicated contraction at the outlet and might pass unnoticed until late in labour. Examination of the diagonal conjugate diameter should always be attempted. It might be difficult in the early months, but was usually possible during the seventh or eighth, especially if the patient "bore down," relaxing the perineal muscles. Short fingers were not really a handicap. The fingers should also sweep round the pelvic brim to detect asymmetrical deformity, a small transverse diameter, or ovarian cysts or fibromyomata. Towards the end of the pregnancy a pendulous abdomen in a primigravida should arouse suspicion. If the head failed to descend into the pelvic cavity during the last month the cause might be faulty presentation, neoplasm, or even placenta prævia, but was often contracted pelvis. The history of previous labours was most valuable. X rays were not of much help, except possibly in the generally contracted pelvis, when Prof. Martin's method was of value.[1] At this stage the fœtal head was the best of all pelvimeters. The method of election, that of Müller, should be performed under an anæsthetic during the last month. In contracted pelvis, however, the position of the head would not indicate how it would mould or alter its position in labour, and Munro Kerr's method of pelvimetry gave a far more reliable prognosis. In labour, if forceps were decided on, a most careful re-examination should be made, if necessary with the hand in the vagina, after the patient had been anæsthetised, and if great difficulty were then apparent the use of forceps should be foregone. Rectal examination was safer than vaginal examination, and just as satisfactory. In borderline cases, if progress were not satisfacory after a good long labour, the lower segment Cæsarean section should be performed.

Occipito-posterior presentations were usually identifiable by careful antenatal examination. Where palpation was difficult two X ray photographs, frontal and lateral, should give a complete diagnosis. Dr. Haultain had secured permanent correction by pads and a binder in 87 per cent. of primigravidæ, and 83 per cent. of multiparæ.[2] 60 per cent. rotated spontaneously, but it was important to recognise the association of this condition with protracted labour. It was often accompanied also by slow dilatation of the cervix. Other abnormal presentations, or the deformities which would cause them, were practically all identifiable before labour. Hydrocephalus was easily detected, except when obscured by hydramnios, and perforation might prevent an exhausting labour. Manual dilatation of the cervix was seldom justified, and, even when attempted, was hardly ever complete.

Antenatal examination of this kind could often be carried out by the general practitioner, but there was need for efficient consulting centres. The work was far too responsible and difficult for midwives, and no midwife should be authorised to undertake the care of a pregnant woman unless provision were made for careful examination by a medical practitioner before labour were due.

Prof. W. Fletcher Shaw remarked on the large number of craniotomies in the series compared with Cæsarean sections, in spite of the increased use of the section by every obstetrical unit. Performed upon a "clean" patient its mortality was very low, but after attempts at forceps delivery it was highly dangerous. Many patients were badly lacerated, and others were shocked; some were definitely infected, and in some cases the child was dead or damaged. Pubiotomy had never become popular, and was only useful when a small amount of widening would make the difference between retention and expulsion. Miscalculation of the amount led to severe laceration.

The main reasons for failure in forceps delivery were professional and lay apathy. Obstetrical teaching was relegated to a subordinate position, and the public did not realise how difficult maternity cases were. Remuneration was poor, and the relatives looked down upon a doctor who called in expert assistance. It was necessary to educate the public and to provide more and sounder clinical teaching. Stress should be laid on four points: antenatal care, asepsis (Prof. Shaw condemned coal-tar derivatives), resistance to the relatives' importunity in the first stage of labour, and definite diagnosis before applying high forceps.

Discussion.

Dr. Charles Douglas (St. Andrews) appealed to general practitioners to shoulder the responsibilities of antenatal work, and warmly recommended version as an effective stand-by when hospitals were far off, with the stringent proviso that the os should be fully dilated. Chloral was very valuable in securing dilatation. Even after forceps had failed, version would often safeguard future maternal efficiency.

Prof. Bethel Solomons (Master of the Rotunda Hospital, Dublin) put most unsuccessful forceps cases down either to abysmal ignorance or to wilful negligence. The first could be removed by training, especially on the management of the all-important first stage; the second should be punished by legal process. Failed cases should be distinguished from cases where forceps had been used tentatively with a view to later pubiotomy or lower segment Cæsarean section. The present curriculum was too short, and an extra year should be allotted to the post-graduate study of obstetrics. He deprecated Dr. Miller's classification of "children dead or dying on admission." It was impossible to tell whether a child was dying, and the impression that it was possible would lead to a far too free use of the cephalotribe. The man who had strength of mind to avoid forceps when contra-indicated, and strength of arm to deliver the head when they were indicated, would have no failed cases. In the Rotunda there had only been 10 in 6000 or 7000 deliveries.

Dr. Mabel Ramsay (Plymouth) viewed craniotomy with horror, and recommended section, even after forceps had failed. Antenatal schemes broke down because the patient would not realise their value; moreover, the officers in charge were often inadequately trained.

Dr. F. Edge (Birmingham) saw a solution in compulsory antenatal consultations with adequate remuneration.

Mr. L. C. Rivett (London) urged four conditions for applying forceps: engagement of the head, full dilatation, passage of the greater diameter through the cervix, and an empty bladder. Neither version nor craniotomy should be performed when the liquor amnii had drained away and the uterus was in an they were characterised by absence of the T-wave and a plateau following the R-wave in lead 2. A few weeks later there was a change. The T-wave was inverted in either lead 1 or lead 3, and was flattened in lead 2, but to a less degree. After 17 months in the case shown there was still inversion widening and notching, but the curve then began to change in the direction of the normal. Eventually normal curves were obtained. One great value of electrocardiograms was that they strengthened the physician's hand when he insisted on prolonged treatment after an attack. Patients often tried to work as soon as the acute stage had passed, and it was important to prevent this.

[2] Proc. Edin. Obstet. Soc., 1926, p. 133.

In the discussion which followed, Dr. Bain said that coronary spasm had been advanced in France as the cause of cardiac pain. It was difficult to see how sclerosed arteries could go into spasm. He would like to ask, however, whether spasm could be the cause of angina without coronary disease.

Prof. T. G. Moorhead (Dublin) was interested in Dr. Coombs's infective group of cases in which angina was associated with phlebitis. He had published a case of thrombo-phlebitis migrans, in which phlebitis had begun in the leg, then attacked various regions of the body, and, finally, coronary thrombosis had occurred. The patient was now in good health.

Dr. A. R. Gilchrist (Edinburgh) called attention to a group of cases in which angina was associated with paroxysmal tachycardia. He doubted whether as much could be deduced from electrocardiograms as was sometimes thought. He had one case which showed inversion of T-waves in several attacks and was diagnosed coronary thrombosis. Post mortem no occlusion of either coronary was found. The pain was probably due to paroxysms of tachycardia. Electrocardiographic records were seldom confirmed post mortem and often none had been taken before the attack.

Dr. Davies, in reply to Dr. Bain, said that coronary spasm was the probable cause of angina. It was doubtless the same lesion as the cerebral angiospastic attacks which caused transient hemiplegia. Alterations in cardiac rhythm were certainly due to thrombosis of the artery to the A.V. bundle.

Dr. Bedford said that it was dangerous to give a prognosis merely from the study of an electrocardiogram. An inverted T-wave could not be said to be of grave import, because it frequently became altered later. He considered low voltage the most serious sign. It was very difficult to obtain postmortems on cases that had been followed electrographically and therefore there was no large series of such cases. In many of his cases, however, the diagnosis had been so confirmed.

Conclusion.

The President summed up the symptoms of coronary thrombosis and described the appearance of the heart in experimental lesions. With regard to prognosis, he agreed with several speakers who had said that the condition was not necessarily a very grave one where there was recovery from the initial attack. In giving a prognosis they had to consider the state of the coronary arteries. A review of the history and the condition of the patient after the event would help in this.

SECTION OF OBSTETRICS AND GYNÆCOLOGY.

At its first session, under the chairmanship of Mr. T. Watts Eden, a discussion on the prevention and treatment of

Unsuccessful Forceps Cases

was opened by Dr. Douglas Miller (Edinburgh), who analysed a group of 558 cases delivered in Manchester, Glasgow, and Edinburgh. In 211, of whom 139 were primigravidæ, the underlying cause of dystocia was *disproportion*, due for the most part to pelvic contraction, and in a few to an abnormally large child. The flat rachitic type of pelvis was exceptionally common in Glasgow. In 14 deformity of the outlet and in 6 a contraction ring provided an additional obstacle. Disproportion varied widely in degree; sometimes it had been difficult to remove the head even when crushed, sometimes labour would have been normal if forceps had been withheld. In 161 patients the cause of difficulty had been a *posterior position of the occiput*, for the most part unrecognised. This fact emphasised the urgent necessity of accurate orientation of the head, for which purpose the ear was a more reliable guide than sutures or fontanelles. In most of these occipito-posterior cases the head had been deeply engaged, with the occiput either in the hollow of the sacrum or still obliquely posterior. In the large number, however, in which the head was still high or movable at the pelvic brim, the soft parts had been severely bruised and lacerated by slipping forceps. In several cases the cervix had been only partially dilated, and was badly torn; sometimes the tear involved the lower uterine segment.

In a third group of 151 cases *no abnormality* had been present. Some of these might have been occipito-posterior before their transit to hospital, but in a large number anxiety to relieve suffering had obviously made the practitioner apply forceps before dilatation and head-moulding had sufficiently advanced. The fourth group consisted of 12 face cases.

Treatment.

Where disproportion was the cause, treatment depended on its degree, the condition of the child, and whether an adequate test of labour had been made; 78 patients of the 211 had been delivered spontaneously or by low forceps. Craniotomy had been employed in 98 cases and Cæsarean section only in 12; 21 of the 29 maternal deaths had been due to puerperal sepsis. Of the 161 cases due to occipito-posterior position the majority were advanced in the second stage with the head arrested on the pelvic floor, and an attempt had usually been made to rotate manually and complete delivery with forceps. When impaction had prevented rotation, craniotomy had usually been performed. In two-thirds of the instances in which the head had been arrested at the inlet of the pelvis, or the upper part of the cavity, manual rotation of the head had been combined with external rotation of the body. Where the os had been found fully dilated, forceps had been immediately put on and delivery completed; when the cervix had not been completely effaced, labour had been allowed to proceed. Internal version, performed as a last resort in 11 of these cases, had saved three of the children.

In most of the 151 cases in which *premature* application had been the only cause of failure, the patient had been placed under *morphine* or twilight sleep and delivered spontaneously or by low forceps. When the child had been dead or dying, craniotomy had been performed.

The *total maternal mortality* had been 54, or 10 per cent.; of these the cause had been sepsis in 37, uterine rupture 8, post-partum hæmorrhage and shock 6, and pneumonia 3. In 132, or 23·6 per cent., the puerperium had been morbid by the B.M.A. standard; 357 children, or 64 per cent., had been lost. Many of the patients had only left hospital after exhausting weeks of fever, and many had had to undergo further weeks or months of ill-health from laceration of the cervix, vagina, or pelvic floor. End-results in 98 patients who had been followed up had been 24 complete recoveries and 74 residual disabilities of varying degree, the most frequent being laceration of the cervix, usually due to application of forceps before dilatation. Backward displacement of the uterus, usually associated with subinvolution, downward displacement, and pelvic infection was common. Pelvic infection occurred in one-third of the cases; 24 patients had had to undergo operation for their resulting disabilities.

Unsuccessful forceps cases resulted largely from the breach of three rules: forceps should never be applied greater among cotton operatives than among the general population at all age-periods. The tuberculosis death-rate shows very little change. Only a very small proportion of the contacts avail themselves of the facilities afforded by the tuberculosis dispensary. It is not practicable with the present staff to arrange for home examination of contacts, but the coöperation of private practitioners would be very valuable in this branch of work. There is great need for adequate after-care for cases of pulmonary tuberculosis.

The antenatal clinic was attended by 480 prospective mothers, the total births being 1702. Dr. Holden is disappointed with the number of patients sent to the clinic by the midwives, who attended 82·4 per cent. of the confinements during 1927. He further points out that no improvement has been brought about by the recent requirement of the C.M.B. that practising midwives should carry out antenatal work or (if they feel unable to do so) send their patients to the antenatal clinic. In 1925 7·5 per cent. of the cases attending the clinic were sent by midwives, in 1926 12·3 per cent., and in 1927 12 per cent. The maternal mortality is high, the figures for the last six years being 6·8, 6·7, 5·0, 5·7, 8·0, and 7·6. The stillbirth-rate for 1927 was 5 per cent. The Springfield Maternity Home has accommodation for 20 cases and is recognised as a training hospital for pupil midwives. The medical officer of health has power to remit the minimum fee of 1½ guineas per week in cases of proved necessity, and there is no reason why any mother, whose home surroundings are unsatisfactory, should not avail herself of the facilities and comforts of the home. Nevertheless the home is not used as much as it might be. There were only 220 cases admitted during 1927, of whom six were for antenatal supervision. From 400 to 500 cases could be readily accommodated.

The death-rate from respiratory diseases among the pre-school children was especially high owing to outbreaks of measles and influenza during the first quarter. Although there has been a distinct fall in the infant mortality-rate since 1920, the death-rate in the 1–5 years group shows no such tendency. Blackburn is more fortunate than most industrial towns in its housing conditions. There is no real slum property and no universal overcrowding, the average rooms per person being 1·1. And yet there is a long list of applications for corporation houses, occasional overcrowding caused by subletting, and a growing tendency for tent sheds and caravans to be used as substitutes for houses.

Bolton.

Dr. C. W. Paget Moffatt reports that for the first time since 1922 the Registrar-General has estimated an increase in the population of Bolton, which makes it nearly as high as it was in 1909—viz., 178,667. The scheme for the substitution of water-closets for privy middens has slowed down owing to difficulties as to sewers and prospective demolition of property.

Bolton is coöperating with the Manchester regional smoke-abatement committee. The intention is to have the same by-laws in all the areas of the region, but up to now the regional committee has not been able to formulate by-laws acceptable to the Ministry. There are 226 factory chimneys in Bolton, and Dr. Moffatt thinks there will be no real abatement of the smoke nuisance in industrial areas until soft coal is replaced by smokeless fuel, and that a great deal will be accomplished in this direction before long. By-laws are needed for houses let in lodgings. Strenuous efforts are being made to reduce the nuisance from vans. At the close of 1927 there were 42 living vans as compared with 73 at the close of 1926. Most of the slaughtering in Bolton is done in private slaughter-houses owing to the fact that the public abattoirs are too small and out of date. The new houses erected were 510 municipal, 490 subsidised houses by other persons, and 81 unsubsidised, a total of 1081. Overcrowding is not prevalent and the number of inhabitants per house has decreased steadily from 4·64 at the census of 1901 to 3·86 in 1927. Forty-seven houses were demolished during the year.

The meat regulations have brought about a marked improvement in the handling of meat, but attention is drawn to the very insanitary practice of leaving the feet on the dressed carcasses of lamb and mutton. The frequently filthy condition of the feet is liable to cause dangerous contamination of the meat.

About three-fifths of Bolton's milk comes from 2700 cows stalled in the borough; one-fifth from outside farms is pasteurised by the Coöperative Society; and the remaining fifth comes from other outside farms. The "inside" cows are regularly inspected by the veterinary surgeon, who is usually accompanied by a sanitary inspector to look after the hygienic condition of the dairy farm. As the result of routine veterinary inspection, 6 cows giving tuberculous milk were found and slaughtered. The cows slaughtered under the Tuberculosis Order numbered 32, of which 9 had tuberculosis of the udder, 1 was giving tuberculous milk and had other tuberculous lesions, 6 showed tuberculous emaciation, and 16 had chronic cough and definite signs. One farmer was fined £5 for failing to notify a cow suffering from tuberculosis of the udder.

Dr. Moffatt shows that Bolton is doing everything recommended by the Ministry for the prevention of maternal deaths, but expresses his opinion that a real improvement in the training and status of midwives is needed. A longer and more thorough training would help to exclude from the profession those who adopt it, not as their real life's work, but as a means of adding to the family income.

Bury.

Dr. G. Granville Buckley says that the scheme for the conversion of privies into water-closets has made rapid progress, but that there are about 450 which cannot be dealt with as there is no sewer available. The sewage disposal works have three systems following the sedimentation tanks—namely, single-contact beds, percolating beds, and the activated sludge process. During 1927 six samples of the joint effluent were satisfactory and two slightly unsatisfactory, as judged by the inspectors of the Mersey and Irwell Joint Committee. The public abattoir is modern in every respect. Of the carcasses, bulls were affected with tuberculosis to the extent of 2·5 per cent.; oxen, 0·21 per cent.; cows, 10·25 per cent.; heifers, 0·55 per cent.; and pigs, 4·22 per cent. The infant deaths numbered 62, and there were 34 deaths of children between the ages of 1–5. Of the three deaths making up the maternal mortality one was due to puerperal fever, another to "septic abortion followed by peritonitis and septicæmia set up by douching in an attempt to procure abortion," and the third to "septic abortion following on accidental abortion. Peritonitis (general)." There was a fourth maternal death of a woman, who had attended the antenatal clinic and who developed kidney trouble the tenth day after labour.

Eccles.

Dr. J. E. Spence points out that there were no deaths of children aged 1 to 2 years from gastro-enteritis in 1927, but that 13·3 per cent. of the deaths at this age-period since 1914 have been due to this cause. The fall in mortality at the age-period 2 to 5 has not been regular, but shows fluctuations caused by the respiratory diseases. Since 1914 28·1 per cent. of the deaths in this age-group have been due to bronchitis and pneumonia, 15·9 per cent. to measles, and 8·4 per cent. to whooping-cough. The child welfare work and school medical work is closely coördinated. Each health nurse attends the centre on one afternoon a week and, as far as possible, the mothers in her area come on that afternoon. Each child during its first year is seen by the nurse on ances of encephalitis lethargica and post-vaccinal encephalitis, together with the fact that lesions comparable with those found in natural disease can be reproduced experimentally in animals by the inoculation of virus containing material, is strong evidence that the encephalitis is actually produced by the infecting virus in each of these two conditions.

Dr. J. G. **GREENFIELD**'s paper was read in his absence by Prof. **HADFIELD**. He dealt with encephalomyelitis in measles and pointed out that this complication appeared to be increasing in recent years. He described in some detail the post-mortem findings in a girl of 9 years in whom there developed convulsions, high temperature, and coma four days after the measles rash had appeared. The similarity of the findings to those in post-vaccinal encephalitis were demonstrated.

Dr. S. P. **BEDSON** considered some aspects of the experimental side of the problem. He pointed out that the virus of herpes febrilis should be carefully considered in dealing with nervous manifestations in virus diseases. This virus has been considered by some authorities to be the causal factor in encephalitis lethargica, such view being based on the isolation of the virus of herpes febrilis from such cases. In encephalitis lethargica, however, no skin lesions occur. Dr. Bedson claimed that an antibody is developed in herpes infection, but he could find no such antibody in encephalitis lethargica. The herpes virus is highly neurotoxic in rabbits, and further, spontaneous encephalitis also occurs in these animals. Great care is therefore necessary in interpreting results.

Prof. G. **HADFIELD** (London) described the appearances in a case of post-vaccinal encephalitis. He had also studied in detail the nervous system of four children who had died from accidental causes shortly after vaccination. In these cases no changes were found. The histological picture in the encephalitis case corresponds with that of other workers. The importance of investigating the condition and reaction of the neuroglia was emphasised. The histological picture in post-vaccinal encephalitis seems to be standard but not specific because of similarity in measles and small-pox. In early lesions of disseminated sclerosis there is histological similarity to the above lesions, but the clinical features suggest a different ætiology.

Prof. J. H. **DIBLE** (Cardiff) expressed considerable doubt on the interpretations of experimental work in encephalitis lethargica. He said that in the rabbit the positive results obtained were inextricably mixed up with the herpetic virus. If herpes and encephalitis virus are the same thing then it exhibits different properties in human and rabbit brains. It is impossible to produce keratitis with fresh material from encephalitis cases, but when encephalitis has been produced in rabbits the virus recovered from the brain will produce keratitis. Clinically, encephalitis rarely or never presents herpes. Herpes is common in pneumonia, but cerebral affection is absent or rare in this condition. Prof. Dible, Flexner, and others had failed to infect rabbits with encephalitis lethargica. Flexner had also failed to infect monkeys. Those who have produced apparently positive results show marked disparity in the time of incidence, and it is difficult to believe that one and the same virus could exhibit such eccentricities. The speaker expressed doubt that the condition of encephalitis lethargica has ever been transmitted to animals.

Prof. J. **CRUICKSHANK** (Aberdeen) drew attention to the incidence of herpes infection in bacterial diseases, and sought information on the incidence of encephalitis in such cases. He further described an interesting happening in which a stock of calf lymph which was used without ill-effects in Spain, when used in Holland produced a number of cases of post-vaccinal encephalitis. Was this the result of a dormant virus being stimulated?

Prof. **McINTOSH**, in reply, said he was quite satisfied that the lesions he had obtained were not those of herpes febrilis or spontaneous encephalitis.

The **PRESIDENT** summed up the discussion which, he said, had brought out clearly the fact that a form of encephalitis was definitely associated with vaccination. Whether the vaccine was the actual cause of the encephalitis or whether it served merely to light up an already existing latent infection was not important from the practical standpoint. If one man assaulted another with a fatal result, the fact that the victim might not have died had he not suffered from heart disease would not save the assailant from punishment. Similarly, vaccination could not be held blameless even if it only lighted up a latent infection. The existence of cases of encephalitis following vaccination was now established, but official figures as to the proportion these cases bore to the total number of vaccinations performed were not available. Since allusions to the complication had frequently appeared in the lay press, he had hoped that the discussion would have brought out some information on this point, so that the medical profession would be in a position to reassure the public.

An interesting exhibition of pathological specimens was on view at University College throughout the Association's meeting.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following table gives some 1927 statistics of five Lancashire districts :—

Name of district and estimated mid-year population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Diarrhœa, &c., under 2 years.	Maternal mortality from childbirth.
Blackburn C.B. (124,500)	13·7	14·9	0·88	1·28	4·0	2·2	77/37	7·0	7·6
Bolton C.B. .. (178,300)	15·1	13·8	1·04	1·32	3·2	1·9	75/36	7·4	4·4
Bury C.B. .. (56,770)	13·7	14·3	1·02	1·35	3·8	2·3	79/35	5·1	3·8
Eccles B. . .. (45,390)	15·6	12·7	1·06	1·65	2·3	2·2	61/24	4·2	2·8
Swinton and Pendlebury U.D. .. .. (34,750)	12·2	10·0	0·86	1·14	2·0	1·4	75/40	2·3	4·7

C.B. = County Borough. B. = Borough.
U.D. = Urban District.

Blackburn.

Dr. Oscar M. Holden reports a sunless year with an abnormal rainfall—958 hours of bright sunshine recorded at the corporation hospital as compared with 1114 in 1926, and 43·3 in. of rain as compared with 40·9 in. Dr. Holden thinks the extent of the clay drifts has some bearing on the prevalence of the rheumatic affections, which are a prominent feature in the sickness records. The year was one of depressed industrial conditions with much unemployment in the town's chief industry of cotton weaving and its subsidiary branches. The population of Blackburn reached its zenith in 1914, and in 1927, for the first time since the war, the deaths exceeded the births—namely, by 162.

The respiratory group of diseases bulks most largely in the death returns of the town, and the predominant causes suggested are unfavourable climatic conditions coupled with a dirty atmosphere. Deaths due to respiratory diseases are markedly greater among cotton operatives than among the general population at all age-periods. The tuberculosis death-rate shows very little change. Only a very small proportion of the contacts avail themselves of the facilities afforded by the tuberculosis dispensary. It is not practicable with the present staff to arrange for home examination of contacts, but the coöperation of private practitioners would be very valuable in this branch of work. There is great need for adequate after-care for cases of pulmonary tuberculosis.

The antenatal clinic was attended by 480 prospective mothers, the total births being 1702. Dr. Holden is disappointed with the number of patients sent to the clinic by the midwives, who attended 82·4 per cent. of the confinements during 1927. He further points out that no improvement has been brought about by the recent requirement of the C.M.B. that practising midwives should carry out antenatal work or (if they feel unable to do so) send their patients to the antenatal clinic. In 1925 7·5 per cent. of the cases attending the clinic were sent by midwives, in 1926 12·3 per cent., and in 1927 12 per cent. The maternal mortality is high, the figures for the last six years being 6·8, 6·7, 5·0, 5·7, 8·0, and 7·6. The stillbirth-rate for 1927 was 5 per cent. The Springfield Maternity Home has accommodation for 20 cases and is recognised as a training hospital for pupil midwives. The medical officer of health has power to remit the minimum fee of 1½ guineas per week in cases of proved necessity, and there is no reason why any mother, whose home surroundings are unsatisfactory, should not avail herself of the facilities and comforts of the home. Nevertheless the home is not used as much as it might be. There were only 220 cases admitted during 1927, of whom six were for antenatal supervision. From 400 to 500 cases could be readily accommodated.

The death-rate from respiratory diseases among the pre-school children was especially high owing to outbreaks of measles and influenza during the first quarter. Although there has been a distinct fall in the infant mortality-rate since 1920, the death-rate in the 1–5 years group shows no such tendency. Blackburn is more fortunate than most industrial towns in its housing conditions. There is no real slum property and no universal overcrowding, the average rooms per person being 1·1. And yet there is a long list of applications for corporation houses, occasional overcrowding caused by subletting, and a growing tendency for tent sheds and caravans to be used as substitutes for houses.

Bolton.

Dr. C. W. Paget Moffatt reports that for the first time since 1922 the Registrar-General has estimated an increase in the population of Bolton, which makes it nearly as high as it was in 1909—viz., 178,667. The scheme for the substitution of water-closets for privy middens has slowed down owing to difficulties as to sewers and prospective demolition of property.

Bolton is coöperating with the Manchester regional smoke-abatement committee. The intention is to have the same by-laws in all the areas of the region, but up to now the regional committee has not been able to formulate by-laws acceptable to the Ministry. There are 226 factory chimneys in Bolton, and Dr. Moffatt thinks there will be no real abatement of the smoke nuisance in industrial areas until soft coal is replaced by smokeless fuel, and that a great deal will be accomplished in this direction before long. By-laws are needed for houses let in lodgings. Strenuous efforts are being made to reduce the nuisance from vans. At the close of 1927 there were 42 living vans as compared with 73 at the close of 1926. Most of the slaughtering in Bolton is done in private slaughter-houses owing to the fact that the public abattoirs are too small and out of date. The new houses erected were 510 municipal, 490 subsidised houses by other persons, and 81 unsubsidised, a total of 1081. Overcrowding is not prevalent and the number of inhabitants per house has decreased steadily from 4·64 at the census of 1901 to 3·86 in 1927. Forty-seven houses were demolished during the year.

The meat regulations have brought about a marked improvement in the handling of meat, but attention is drawn to the very insanitary practice of leaving the feet on the dressed carcasses of lamb and mutton. The frequently filthy condition of the feet is liable to cause dangerous contamination of the meat.

About three-fifths of Bolton's milk comes from 2700 cows stalled in the borough; one-fifth from outside farms is pasteurised by the Coöperative Society; and the remaining fifth comes from other outside farms. The "inside" cows are regularly inspected by the veterinary surgeon, who is usually accompanied by a sanitary inspector to look after the hygienic condition of the dairy farm. As the result of routine veterinary inspection, 6 cows giving tuberculous milk were found and slaughtered. The cows slaughtered under the *Tuberculosis Order* numbered 32, of which 9 had tuberculosis of the udder, 1 was giving tuberculous milk and had other tuberculous lesions, 6 showed tuberculous emaciation, and 16 had chronic cough and definite signs. One farmer was fined £5 for failing to notify a cow suffering from tuberculosis of the udder.

Dr. Moffatt shows that Bolton is doing everything recommended by the Ministry for the prevention of maternal deaths, but expresses his opinion that a real improvement in the training and status of midwives is needed. A longer and more thorough training would help to exclude from the profession those who adopt it, not as their real life's work, but as a means of adding to the family income.

Bury.

Dr. G. Granville Buckley says that the scheme for the conversion of privies into water-closets has made rapid progress, but that there are about 450 which cannot be dealt with as there is no sewer available. The sewage disposal works have three systems following the sedimentation tanks—namely, single-contact beds, percolating beds, and the activated sludge process. During 1927 six samples of the joint effluent were satisfactory and two slightly unsatisfactory, as judged by the inspectors of the Mersey and Irwell Joint Committee. The public abattoir is modern in every respect. Of the carcasses, bulls were affected with tuberculosis to the extent of 2·5 per cent.; oxen, 0·21 per cent.; cows, 10·25 per cent.; heifers, 0·55 per cent.; and pigs, 4·22 per cent. The infant deaths numbered 62, and there were 34 deaths of children between the ages of 1–5. Of the three deaths making up the maternal mortality one was due to puerperal fever, another to "septic abortion followed by peritonitis and septicæmia set up by douching in an attempt to procure abortion," and the third to "septic abortion following on accidental abortion. Peritonitis (general)." There was a fourth maternal death of a woman, who had attended the antenatal clinic and who developed kidney trouble the tenth day after labour.

Eccles.

Dr. J. E. Spence points out that there were no deaths of children aged 1 to 2 years from gastro-enteritis in 1927, but that 13·3 per cent. of the deaths at this age-period since 1914 have been due to this cause. The fall in mortality at the age-period 2 to 5 has not been regular, but shows fluctuations caused by the respiratory diseases. Since 1914 28·1 per cent. of the deaths in this age-group have been due to bronchitis and pneumonia, 15·9 per cent. to measles, and 8·4 per cent. to whooping-cough. The child welfare work and school medical work is closely coördinated. Each health nurse attends the centre on one afternoon a week and, as far as possible, the mothers in her area come on that afternoon. Each child during its first year is seen by the nurse on an average 29 times, during the second year 8·9 times, and during the third year 4·8 times. The supervision continues during the 3–5 age-period, when about half the children attend school. Early treatment of the pre-school child for squint, dental trouble, and other ailments is thus made possible. "Ultra-violet" treatment is provided at Barton-upon-Irwell Hospital for rickets and debilitating conditions, but Dr. Spence is not greatly impressed with its value, if separated from other hygienic measures. There is a difficulty in getting the "lazy, indolent mother" to persevere with any treatment for rickets, as she trusts to the deformities disappearing without treatment and does not appreciate that the deformity is only one effect of the disease. The water from the two swimming baths is filtered through Bell's filters. The men's bath was closed for repairs after the water had been in use from January, 1923, until Oct. 31st, 1927. During the whole of this period the chemical and bacteriological examination of this water was satisfactory. The women's bath is chlorinated as well as filtered, but the analysis taken on Sept. 20th shows more chlorine in the water of the men's bath than in that of the women's. Notwithstanding the extensive provision of municipal houses, there are too many houses occupied by more than one family, and many cases of hardship therefrom. The rent charged to the lodging family in many instances exceeds the rent of the whole house. During the year 19 municipal houses, 34 subsidiary houses, and 3 houses of a larger type were erected, while 24 houses were demolished. Ninety municipal houses are nearing completion, and the corporation are considering a scheme for 68 more. There are 800 families which still require to be housed and there are no signs of the shortage of houses being overtaken.

Swinton and Pendlebury.

Dr. H. C. Mulholland, who is also school medical officer and certifying factory surgeon to the urban district, says the staff engaged upon orthopædic, dental, and aural work for the schools does similar work for the maternity and child-welfare centres. The district, except in a few outlying cases, is on the water-carriage system. The sanitary inspectors have been sent for a course of special training in dairying. A table shows that out of 52 routine samples of mixed milk, tested by biological methods, nine contained tubercle bacilli. Systematic veterinary inspection of the farms has been in force since 1924, and the veterinary surgeon is accompanied by the sanitary inspector, who sees to the sanitary condition of the dairy farms. The council has adopted the limit of 2 minutes in the half hour for black smoke, and legal proceedings were successfully taken and fines inflicted during the year in three instances. Since 1920, 32 cases of encephalitis lethargica have been notified, including one doubtful case in 1927. The present condition is that 8 have died, 17 are severely ill, 4 are slightly ill and fit for light work, and 3 are apparently normal. There was no evidence that case-to-case infection, insanitation, or overcrowding were causal factors. The health visitors have undergone a short course of training at the Manchester Royal Eye Hospital on the nursing of ophthalmia neonatorum. The four cases notified in 1927 all made a complete recovery. One urinary typhoid carrier resident in the district is kept under observation, but did not give rise to any cases in 1927. There were 709 births, and 81 expectant mothers attended the antenatal clinic, which is conducted by a consultant. Caravans tend to increase in the district, and the occupants are usually dependent upon neighbours for water and sanitary conveniences. There are just over 5000 working-class houses in the district, and 309 of these houses are overcrowded. Houses needed are estimated at 510, 210 for the unsatisfied demand, and 300 to provide for the demolition of insanitary property. No council houses were completed during the year, but 182 are in course of erection.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JULY 21ST, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 173 (last week 177); scarlet fever, 1528; diphtheria, 900; enteric fever, 54; pneumonia, 706; puerperal fever, 43; puerperal pyrexia, 94; cerebro-spinal fever, 7; acute poliomyelitis, 5; acute polio-encephalitis, 4; encephalitis lethargica, 21; dysentery, 3; ophthalmia neonatorum, 130. No case of cholera, plague, or typhus fever was notified during the week.

The cases of small-pox were notified from the following 19 counties:—London, 9; Buckingham, 1; Derby, 12; Durham, 53; Essex, 3; Huntingdon, 1; Kent, 1; Lancaster, 5; Northampton, 1; Northumberland, 12; Nottingham, 2; Soke of Peterborough, 2; Stafford, 11; Surrey, 1; Yorks East Riding, 3; North Riding, 12; West Riding, 24; Glamorgan, 13; Monmouth, 7.

The number of patients in the Infectious Hospitals of the *Metropolitan Asylums Board on July 24th–25th was* as follows:—Small-pox, 23 under treatment; scarlet fever, 1771; diphtheria, 1849; enteric fever, 19; measles, 303; whooping-cough, 196; puerperal fever, 18 (plus 12 babies); encephalitis lethargica, 67; poliomyelitis, 2; "other diseases," 22. At St. Margaret's Hospital there were 21 babies (plus 11 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 5 (1) from enteric fever, 28 (5) from measles, 5 (3) from scarlet fever, 20 (1) from whooping-cough, 26 (8) from diphtheria, 36 (9) from diarrhœa and enteritis under two years, and 21 (2) from influenza. The *figures in parentheses are those for London* itself.

The four fatal cases of enteric fever outside London were reported from Southampton, Sunderland, and Newcastle-on-Tyne (2). Of the 23 fatal cases of measles outside London, 6 were reported from Liverpool. Of the 19 cases of whooping-cough outside London, 3 were reported from Birmingham. In the same week Glasgow reported 6 and Belfast 4. Belfast also had 6 fatal cases of measles. The deaths from *diarrhœa are still diminishing.*

The number of stillbirths registered during the week was 270 in the great towns (corresponding to a rate of 38 per 1000 births), including 53 in London.

Deaths from Small-pox.—A supplementary monthly statement shows that the returns for the month of June included, in addition to the deaths already shown in the Weekly Return, 6 deaths certified as due to small-pox either as principal or contributory cause. These deaths were assigned to the following areas:—Ilfracombe U.D., 1; King's Lynn M.B., 2; Thame U.D., 1; Keighley R.D., 1; and Gelligaer U.D. (Glam.), 1.

HERTFORD BRITISH HOSPITAL, PARIS.—The King and Queen have given their patronage to this hospital, which was founded during the seige of Paris in 1871 by the late Sir Richard Wallace. In 1879 Sir Richard erected a new building which his widow handed over to the British Government. The British Ambassador in Paris for the time being is the honorary president. The hospital is situated at Levallois-Perret, outside the fortifications, and has 46 beds.

EXTENSION OF LEEDS GENERAL INFIRMARY.—Particulars are now available of the proposed large extensions of this institution which, together with the discharge of the bank overdraft, will cost £250,000. There is to be a paying patients' block of three floors in which patients will pay some 5 to 7 guineas a week, according to the degree of privacy enjoyed. It is hoped that this block will help to remove the difficulties caused by the rapid growth of motor accident cases which are costing the infirmary £1000 a year, while the donations traceable to those concerned amount to less than £100. Another block, which is to be built first, will provide for another 100 non-paying patients—the waiting-list has rarely less than 1000 names. The building of these two new blocks will increase the total accommodation of the infirmary itself and the branches at Cookridge from 632 to 800 beds. The present average annual deficit is £25,000 and the extensions will increase the cost of maintenance from £104,000 to £120,000 a year.

Special Articles.

MEDICINE AND THE LAW.

Death Certification: Date of Certifying Practitioner's Last Visit.

THE primary purpose of the coroner's inquest is one of public safety—the detection of foul play, and consequently the prevention of crime. The result of the amending legislation of 1926 was to interlock the law relating to coroners and the law relating to the certification of death. It now is, or should be, as difficult as human foresight can make it to conceal a death or to dispose of a body without adequate official knowledge of the circumstances of the death. It also is, or should be, as difficult as human foresight can make it to dispose of a body by burial or cremation when death has not in fact taken place. These safeguards for the public have naturally not been evolved without enacting an elaborate code of statutes and regulations. There is some reason to think that medical practitioners, on whose coöperation the whole system depends, are not yet fully aware of the new legal position. The Registration Act of 1926 provided for a "prescribed" form of doctor's death certificate, and the form thus prescribed requires the doctor to state when he last saw the patient alive. Part IX. of the new regulations—the Registration (Births, Stillbirths, Deaths and Marriages) Consolidated Regulations of 1927—is headed, "References to Coroner and Registration after Reference—Stillbirths and Deaths." One of the occasions on which the registrar must report to the coroner before registering a death is where "it appears to the registrar from the particulars contained in the medical certificate or otherwise that the deceased was seen by the certifying medical practitioner neither after death nor within 14 days of death." Those who are apprehensive of the risk of a person being buried alive will reckon this regulation as intended to avert that danger as well as to lessen the chance that death might be caused by violence or poisoning in the interval between the practitioner's last visit and the date of death.

At a recent inquest, held in Southwark by Dr. F. J. Waldo upon the death of a woman aged 81, the coroner explained that the case had been reported to him by the registrar under the regulation already cited. It appeared that the medical practitioner had certified death to be due to natural causes, and that his last attendance had been seven weeks before the date of death. In these circumstances the coroner ordered a full post-mortem examination by an independent pathologist, and requested the attendance of the certifying doctor at the inquest. The pathologist's evidence agreed with the certificate, and thus the inquest merely confirmed what was already upon record. In answer to the coroner the pathologist agreed that, without careful expert examination of a body, it was not safe to assume that death had actually taken place. He cited an instance where the police had recently called him in to examine a youth in a state of catalepsy. The patient appeared dead but, on examination, a feeble pulse beat was found in spite of commencing rigor of the muscles of the jaw, absence of eye reflex, and dilated pupils—three characteristic signs of death; appropriate treatment ended in recovery. Dr. Waldo, in summing up, described the state of the law in connexion with death certification, registration, and disposal of the dead as unsatisfactory and dangerous. It was, he said, of vital importance to the public that the view and external examination of the body by the certifying doctor should be made compulsory before burial. Such a course would be a safeguard against any possible false assumption of death. Dr. Waldo's point is that a statutory period of 14 days, without any further view of the body, is neither a safeguard against premature burial nor a trustworthy precaution against the non-detection of foul play. He would have the present law amended in the following three respects: first, compulsory view of the body by the certifying practitioner who attended the deceased (with payment of a small fee for such duty) prior to registration of death by the local registrar; secondly, registration without report to the coroner, provided the certifying doctor had last attended his patient within 14 days of death and had also viewed the dead body; thirdly, statutory notification by the registrar to the coroner of all deaths of patients not seen by the certifying doctor within the 14 days period, to be followed by public inquest.

It is probably a surprise to some practitioners to find that coroners can, and do, order *post-mortem* examination and inquest where the certifying doctor has not seen the deceased within 14 days of death. Each case must be judged upon its own set of facts, and it may well be that one coroner would not take the same view of his responsibilities as another. Whether the law will soon be changed is doubtful. Parliament has only lately hammered out the new changes, and the arguments for different changes were fully discussed when the present ones were adopted. Sir Kingsley Wood, replying to a question by Mr. T. E. Naylor, M.P. for Southwark, in the House of Commons on July 11th, held out no prospect of further legislation at present.

A Point in the Coroner's Law.

A coroner asks a practitioner for certain information as to the cause of death of a deceased person to enable him to decide whether or not he will hold an inquest. The information desired in this case was technical both as to fact and opinion, and was given out of professional knowledge and experience. On consideration of the information the coroner decided to hold no inquest, and having held no inquest he paid no fee. Quite amicably, the doctor and the coroner have sought our opinion, or reference to any opinion that has been previously expressed in similar circumstances. The doctor considers that a fee is due to him, and the coroner, allowing the justice of the claim, replies that he has no power under the law to satisfy it.

It seems to us clear that the doctor should be paid, and equally clear that the coroner should not be at the expense of a fee for which he would be surcharged. A sentence in the Statute would suffice to meet the case, but changes in an Act of Parliament are not readily brought about; and while the situation may occur with sufficient frequency to suggest a demand for legislation, it is not clear to us that the existing position is not preferable. The doctor who supplies the coroner with the needful information is relieved of a responsibility to give medical evidence, and many practitioners would welcome this, while the relatives are spared a procedure that they always dislike unless they have reason for promoting an inquiry. In all such cases the coroner would know the feeling of the family and would hold the inquest. One natural source for the fee would be estate of the deceased, if there were any estate, but executors could not be bound to admit the doctor's claim.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Settlement of a Conflict Between the Profession and a Sick Club.

WITHIN the last few weeks a serious conflict arose between the entire medical profession in Vienna and the vast organisation called the Sickness Insurance Club for Civil Servants. This latter has about 280,000 members, and had hitherto offered free choice of practitioners to its members. Recently the administrative body of this club has tried to remove the bulk of the profession from the free choice list; doubtless the intention was gradually to substitute for the free choice system—advantageous both to the profession and the patients, but not to the administrative body—a system of appointed doctors responsible only to the board of the club. As the remonstrances of the medical representatives were useless, from June 11th all medical work for the club was refused, and the members were received only as private patients. They were, however, entitled to demand compensation and a refund of the fees paid to the sick club. This led to troublesome conditions for all parties concerned, but mostly for the managing board, so that after some three weeks it was found more convenient to arrive at an understanding. The arrangement provides that in future the board of the club will not seek to introduce innovations of any kind pertaining to therapy without the consent of the medical representatives; the extent of specialist service to be available will be controlled by a board chosen equally by the club and the profession. Some minor problems were settled at the same time, in a sense favourable to the practitioners, so that this strike—the first instance of a medical fight on the lines of trades-unionism in this country—can be looked upon as having ended in favour of the doctors.

Decapsulation of the Testicle as a Means of Rejuvenation.

Intense public interest seems to be aroused by any suggested methods of regaining lost youthfulness. Prof. Ullmann (Vienna) has now published his observations on the method of "decapsulation," practised by him since 1915, but hitherto unpublished. He has had the opportunity of making transplantations of testicles in cases of ectopia testis, and of examining such cases after a few years. In each case new blood-vessels had formed, but only if the transplantation took place in individuals belonging to the same blood group or a related one. Otherwise the transplanted organ was gradually absorbed. This he holds to be the fate of the testicles transplanted from monkeys or other animals (Voronoff). In such cases transplantation acts only as a stimulus, like a non-specific protein injection. Ullmann claims now that the safest and most reliable method of producing lasting hyperæmia—and thus a hyperproduction of the hormones—in the testis is to decapsulate it and thus offer it means to expand, since the primary reason for diminished function of the testes is, according to him, the increasing intra-testicular pressure with lessened blood-supply, due to sclerotic processes. Prof. Ullmann lays stress on the fact that, in 1915, when the problem of blood-group relation was unknown, transplantation was applied in a wrong way, and that now his method, which is very simple, should be tried in suitable cases.

Resignation of Prof. Wagner-Jauregg.

The well-known neuro-pathologist and latest recipient of the Nobel prize for medicine, Prof. Wagner-Jauregg, has resigned his post as chief of the clinic for neurology and psychiatry in Vienna, having attained the age of 71. His farewell lecture, held a few days ago, was marked by a number of farewell speeches from his pupils. The professor himself completed his task by delivering a splendid lecture on the treatment of tabes, after which Prof. Redlich and Dr. Poetzl, on behalf of the former and the present pupils, spoke of the importance of his contributions to the advance of neurology, notably in the prophylaxis of thyroid enlargement and the malarial treatment of general paralysis of the insane and tabes dorsalis. The office of Wagner-Jauregg will be filled shortly either by Prof. Economo (Vienna), well known for his researches on encephalitis lethargica, or by Prof. Poetzl (Prague), the first-named being regarded as the more likely candidate.

Statistics Concerning Suicides in the Half Year 1928.

The public records for the first half of 1928 show that 1528 persons attempted to commit suicide in Vienna, of whom 507 attained their object. These figures show a marked and constant increase in comparison with the years before the war and the period immediately following it, the number of attempts being double those recorded in 1917. It is remarkable that while the same number of men and women tried to kill themselves, only 199 women succeeded in doing so, against 308 men. As regards the causes of suicide, 287 (106 of these were men) tried to destroy their lives for family troubles; 275 (165 men) because of poverty, 160 (80 men) for incurable illness, 160 (55 men) an account of love affairs, 130 persons (78 men) were insane; 41 men and 5 women despaired of their financial position or outlook, 17 men and 22 women were prompted by a severe family loss. In 433 cases (221 men) the reasons were unknown.

American Post-graduate Students in Vienna.

This summer, as usual, a large number of American doctors have made our university their temporary home. In the last week of June a group of over 60 doctors, under the leadership of Prof. George MacKenzie, of Chicago, have been here, having arranged beforehand to attend a number of special courses in the clinics of Profs. Neumann, Hejek, and Masschik (oto-rhino-laryngology) and Profs. Meller and Lindner (ophthalmology). These classes will last six weeks each, and will occupy ten hours daily, so that each student will obtain 300 hours of instruction. These zealous post-graduate students, in order to fit themselves to make the most of the instruction provided, attended classes conducted by Prof. MacKenzie, as an introduction to oto-rhino-laryngology and ophthalmology. Post-graduate courses in Vienna are much favoured by the Americans; already more than 300 have put down their names for courses in the session 1928–29. A special American Medical Association of Vienna controls and organises these courses, which are held in English.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Venereal Diseases.

IN Dr. William Robertson's report on the health of Edinburgh in 1927 reference is made to venereal diseases and to the House of Common's refusal of a second reading to the Corporation Bill. The report notes that certain forms of disease are on the increase despite all that has been said and done to educate the public. It is unfortunate that moral and social questions have been introduced to hamper us in our efforts to control the spread of these dangerous infections. Venereal diseases are much more serious than other maladies because, if incompletely treated, they may have disastrous after-effects. It was because we are aware of the serious consequences to the individual and to future generations that we desired to secure a better control of the disease in its different forms and phases. We may as well cry for the moon to come down to earth as expect to get the better of venereal diseases by voluntary methods. The great majority of infected persons will continue to present themselves for treatment, but unless we have the power to compel those who are indifferent, careless, or obstinate to rid themselves of the disease we must expect to find a continuation of mental deficiency, affections of the nervous system, miscarriages, as well as chronic and often indefinable ill-health among men, women, and children. Our effort has been arrested by dialectics. Those who have experienced the difficulties and understand the problem from actual contact with it have been seriously discouraged though not disheartened.

The Slaughter of Sheep.

A report on the investigation carried out in Edinburgh on June 14th has now been issued by Dr. Henry Dryerre, Professor of Physiology at the Royal

Dick Veterinary College, and Dr. J. D. S. Cameron, Physician to the Royal Dispensary. They state that 60 sheep were provided, and at their request the suggested methods of slaughter were amended and ordered as follows: (1) sticking and checking, 20 sheep; (2) shooting and sticking, 20 sheep; (3) shooting and sticking, and breaking of the neck, 10 sheep; (4) sticking and checking, 10 sheep. In the determination of when consciousness was lost, they based their conclusions upon the disappearance of certain cerebral reflexes. They give it as their opinion that shooting and sticking is much to be preferred to sticking and checking, from the humanitarian point of view and, further, that after shooting, no humanitarian benefit is derived from checking or neck-breaking. They realise that sticking is necessary from the utilitarian point of view, and no objection can be taken to this procedure, on the grounds that it produces pain, if shooting precedes it.

The Scottish Health League.

A meeting of the provincial council of the Scottish Health League was held recently in Glasgow, with Prof. Carstairs Douglas in the chair. A large and representative General Council was elected, including many well-known members of the medical and dental professions, together with 94 medical officers of health throughout Scotland. Colonel P. S. Lelean, Professor of Public Health in the University of Edinburgh, was elected chairman, and Dr. A. K. Chalmers, vice-chairman of the General Council, with Dr. David McKail hon. secretary. The following Executive Council was elected: Dr. M. Adams McVey, L.D.S., Dr. Thomas Adam, Dr. G. G. Buchanan, Dr. Agnes Cameron, Mr. J. Menzies Campbell, L.D.S., Dr. A. K. Chalmers, Prof. Carstairs Douglas, Dr. R. C. Scott Dow, L.D.S., Dr. James Kerr, Prof. P. S. Lelean, Dr. G. W. McIntosh, Dr. David McKail, Dr. G. V. T. McMichael, Dr. J. Hume Patterson, Dr. D. L. Radford, L.D.S., Dr. G. Y. Richardson, Dr. T. Lauder Thomson, Dr. Margaret Tod, and Dr. Chalmers Watson.

The Council intends to form an advisory council, and health societies and social organisations operating in Scotland have been invited to nominate representatives. It has been decided to inaugurate branches of the League throughout Scotland, and it is hoped that all interested in the dissemination of knowledge upon healthy living will coöperate with the Council.

Larbert Colony Scheme for Adult Mental Defectives.

The directors of the Royal Scottish National Institution, Larbert, are appealing for support towards the colony now being established at Larbert Estate for the whole-life care of adult mental defectives. For the last 65 years the Royal Scottish National Institution has provided a home, care, and training for mentally defective children, of whom there are at present over 500 in the home; but these children have to be discharged on arriving at the age of 16 or 20. The directors emphasise the dangers which this involves both for the mentally defective themselves and the community. The colony scheme has been adopted by every other progressive country, but has not hitherto been attempted in Scotland.

Students' Attitude to Charity.

Edinburgh students have recently been considering a proposal that they should run a "Charities Week" of their own instead of merely helping the organisers of the Royal Infirmary pageant on Infirmary Day. The suggestion, which was discussed by the students' representative council, has not met with general approval. Such efforts are made annually in Glasgow and Aberdeen, and they have hitherto met with great success. In deciding not to follow the example of the students of these two cities, the Edinburgh students were of opinion that the idea of collecting for charity was being carried too far. In Glasgow, for instance, the students started quite modestly. But they always set themselves out to beat their previous total, with the result that the campaign is now gigantic, and they find themselves committed to a big piece of organisation. Necessarily they have only a limited amount of spare time. It is no longer an enjoyable rag, but a serious, arduous campaign, with months of preparation. Again, in Glasgow and Aberdeen the infirmaries do not organise pageants of their own as is done in Edinburgh, and the concerted effort of the students is the only one of the year in these cities.

The students will, of course, continue to do their best on Infirmary Day.

The Trend of Medicine.

The place which the physician has held in the world in the past and the place which he is likely to hold in the future were touched upon by Prof. William Wright Smith, in the course of an address at the summer graduation in medicine at Edinburgh University on July 18th. The trend of medicine, he said, was to the prophylactic. In the plant world it had been realised long ago that cure was at best difficult—prevention was the aim. How would these changes affect them in the public eye? We were still far, perhaps, from the institution of a scientific medical police. But would the tendency be for the medical man to become more and more of an official? Officials were not loved. But as long as the ethical obligations, so characteristic of the past, continued on the same high level, the favourable status of the profession was assured.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. D. G. Addison-Scott is placed on the Retd. List with rank of Surg. Capt.

Surg. Comdr. T. C. Patterson to *President*, for Medical Dept., temp.

ROYAL NAVAL VOLUNTEER RESERVE.

Prob. Surg. Lts. R. Pedlow and W. T. Donovan to be Surg. Lts.

ROYAL ARMY MEDICAL CORPS.

Capts. to be Majs.: C. B. C. Anderson, P. E. D. Pank, and G. Moulston.

ARMY DENTAL CORPS.

Temp. Capt. W. L. Pearson, Dental Surg., Gen. List, to be Capt.

Lt. (on prob.) R. W. Mather is confirmed in his rank.

TERRITORIAL ARMY.

Capt. E. Scott to be Maj.

J. R. Wright and G. C. Vaughan to be Lts.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Army Dental Corps.—Lt. H. G. L. Fletcher, from T. A. Res. of Off. (5th Bn. Foresters), to be Lt.

ROYAL AIR FORCE.

The temp. commn. of Flying Officer S. McC. Craig (temp. Lt., Gen. List, Army Dental Surgeon) is terminated on relinquishment of his Army commission.

RESERVE OF AIR FORCE OFFICERS.

Flight Lt. W. D. Miller is transferred from Class D2 to Class D1.

INDIAN MEDICAL SERVICE.

Capt. D. R. Thomas to be Maj.

Nand Lal Sah and Bhawani Das Sindhwani to be temp. Lts.

The undermentioned retire: Maj.-Gen. A. A. Gibbs and Lt.-Cols. H. Watts and W. Lapsley.

TERRITORIAL DECORATION.

The King has conferred the Territorial Decoration upon Majs. R. I. Dacre, A. Young (ret.), and W. T. Briscoe.

Birmingham Children's Hospital.—The board of governors report that during the first six months of the present year the number of patients admitted was 2798, nearly 250 more than in the same period last year. The waiting-list exceeds 700, and two new wards are to be built to provide 40 more beds, together with an isolation block.

CANCER: VIRUS OR ENZYME?

To the Editor of THE LANCET.

SIR,—After what we have suffered at the hands of too imaginative reporters, it is refreshing to read your admirable leading article under the above title. At no time have we suggested that cancer in general is due to an enzyme. All that Dr. Murphy and I have claimed is that a certain tumour of fowls, commonly known as Rous Sarcoma No. 1, is produced by a chemical substance of enzymic nature and not by a virus in the ordinary acceptation of the word. I am a little surprised at your verdict that "the essential problem presented by the filterable tumour of the fowl is not whether the causative 'agent' is a virus or an enzyme." My memory may be playing a prank on me, but I seem to recollect that just three years ago you wrote in an article which was quoted all over the world, that the conclusions of Gye and Barnard provided "a solution of the central problem of cancer." These conclusions were based entirely on the belief that the same chicken tumour agent was a *virus*. If it is an enzyme, then the whole theory fails.

In the annual report of the British Empire Cancer Campaign, published on July 9th, I mentioned that I had once induced the Rous sarcoma by the injection of minced normal fowl pancreas, but I did not feel inclined to attach undue importance to it, as it was a solitary observation. It was only when my friend, Dr. Murphy, informed me of his more recent and more extensive experiments that I urged him to communicate them briefly to the International Conference on Cancer. When these are published in detail I think they will supply the information you desire.

The demonstration of the enzymic nature of the chicken-tumour agent, as you very well say, "would not in itself solve the problem of malignancy, but would rather present us with a phenomenon of far-reaching significance in its general biological aspects." My recent communication shows that I have realised this, and I can assure you, Sir, that although Dr. Murphy did not discuss it in his paper, he is well aware of the implications.

I am, Sir, yours faithfully,
ARCHIBALD LEITCH.

Cancer Hospital Research Institute, Fulham-road, S.W.,
July 30th, 1928.

"CARDIAC CLINICS."

To the Editor of THE LANCET.

SIR,—I shall be glad to be allowed space to comment on the letter from Dr. W. Robert F. Collis which appears in your last issue (p. 199).

1. I do not think that it should be said that in England we are apt to regard America as free from juvenile rheumatism. On the contrary, American reports and papers have been much studied here and, as their value deserved, widely quoted.

2. It is good to read of Dr. Collis's enthusiasm for special clinics for the study of rheumatic heart disease in children, but we are not, perhaps, as far behind in this matter here as he thinks. Glasgow was the first in the field, but there are now in the metropolitan area of London seven such centres (see *L.C.C. Gazette*, July 16th, 1928); and there are others, probably many others, in the provincial cities and big towns. In most cases such centres are attached to hospitals and are under the direction of one of the physicians on the honorary staff, but two of the seven London ones are under the care of Dr. Dobbie, of the L.C.C. Medical Service. As only 15 months have elapsed since the publication of the second report of the British Medical Association Committee on Rheumatic Heart Disease in Children, in which the establishment of such centres in connexion with hospitals was advocated, I think the response of the voluntary hospitals has been extremely good.

3. I still hold that to call such centres "cardiac clinics for children" is, in spite of the alluring alliteration, the greatest possible mistake. As the B.M.A. Committee considered, unless the word "rheumatism" is included in the title, attempts at the prevention of rheumatic heart disease are bound to be handicapped. What the poor make of the word "cardiac" I do not know, but certain it is that hospital parents, although they may know that their child has rheumatism, hardly ever suspect the presence of heart disease. For this reason most of the clinics have in England been called "rheumatism supervisory centres." This tends, no doubt, to fill the clinic not only with "potential cardiacs," but even with "potential rheumatics," yet, surely, the right way to study rheumatic heart disease in children is in terms of the great systemic infection rather than as a static disease of a single organ.

4. In a less important and personal matter, I beg leave to state that I have never held nor expressed the view which Dr. Collis attributes to me, that "the environmental factors at work (of which cold and damp are the most important) must to some extent centre round the production of disease-infected tonsils." The phrase in brackets does not occur in my paper, nor does it correspond with anything in my mind.

As this exaggerated view has been attributed to me before in your correspondence columns and militates against the success of much for which I am striving, I should like to add that to call attention to cold damp as a possible factor in the production of juvenile rheumatism is no reason for my being credited (or debited) with the view that this is the chief thing operating. I hold that there are half a dozen predisposing factors, and where these "click" (as the saying is) there develops juvenile rheumatism. Of these factors, exposure to cold damp is one—sometimes absent, but often important.

I am, Sir, yours faithfully,
Harley-street, W., July 28th. REGINALD MILLER.

GLYCERINE IN THE TREATMENT OF SUPPURATIVE OTITIS MEDIA.

To the Editor of THE LANCET.

SIR,—When house surgeon to the Royal United Hospital, Bath, in 1884, it was difficult to treat satisfactorily cases of suppurative otitis media with the dry dressings then in vogue, because the out-patients were unable to attend with sufficient regularity. Something therefore had to be found for home use. I began with perchloride of mercury in glycerine 1 in 1000. The results were astonishing, recent cases completely recovered in a few days, and chronic cases after having resisted all other known forms of treatment. The value attributed to glycerine is its hygroscopic quality which permits it to search the innermost recesses of the suppurating sinuses with the antiseptic dissolved in it. I mentioned this treatment to my old friend, Prof. Rushton Parker, and we find him at the British Medical Association meeting at Newcastle in 1893 advocating it as routine treatment, on which reliance could be placed. He tried carbolic acid in glycerine, which is equally good. Whether perchloride of mercury or carbolic acid be employed, the glycerine must be neat without the addition of water. One case made a deep impression on me, that of an American who had had a discharge from his left ear for 30 years. There was a large perforation of the tympanic membrane at the lower and posterior quadrant which completely healed and his hearing returned. Now, years after my retirement, I come across cases among acquaintances and friends where all treatment has been given up in despair, but which recover under the glycerine perchloride application.

I am, Sir, yours faithfully,
T. PAGAN LOWE.

Charmouth, Dorset, July 24th.

POST-OPERATIVE MASSIVE COLLAPSE OF THE LUNGS.

To the Editor of THE LANCET.

SIR,—The importance of post-operative pulmonary complications is ably set out by Dr. C. R. Boland and Dr. J. E. Sheret in their paper on massive collapse of the lung, which appeared in your issue of July 21st (p. 111). The clinical description and the radiograms are admirable, but the explanation of the process seems inadequate. If the massive collapse be due to plugging of bronchi why should it be more frequent in upper abdominal operations, why should it be entirely independent of the anæsthetic administered, why should it occur at all ages with equal frequency, and why should it be met with in cases where there is not the least suspicion of bronchitis or increased bronchial secretion?

That a plugged bronchus can cause collapse of the lung is well known; undoubted cases have been seen and described. When a large bronchus is plugged the onset is sudden—absolutely sudden—and the patient becomes immediately urgently ill and cyanosed. The lung slowly deflates, and the patient becomes gradually accustomed to his diminished oxygenating area and regains comfort. Later on he begins to expectorate, and slowly recovers his pulmonary function. The degree of deflation is never as great as that seen in the most severe cases of massive collapse, and the breath sounds over the lung with a plugged bronchus are absent even before deflation has begun. Bronchial breath sounds are not heard. This picture is a complete contrast to that given by massive collapse which follows injury or operation Here the onset of symptoms is more gradual, dyspnœa appears within a few hours of the injury and gets worse, some slight duskiness may be detected, but cyanosis is seen only in the worse cases. Commonly both lungs are affected moderately, often one rather more than the other, usually the right base is the more deflated; but when one lung is affected the degree of deflation is considerable and may be complete. Respiration is quickened and shallow; on the affected side thoracic movement is limited, interspaces are indrawn during inspiration, and the abdomen is rigid. Breath sounds are weak at first, later become bronchial, and in complete deflation are absent except over the lung root.

Of the gunshot injuries which I saw during the late war I still possess records of 666 cases; of these a large number showed some bilateral deflation of the lungs; 30 showed massive collapse of one lung, and nine had complete collapse of one lung. Among many post-mortem examinations were two on men who died (8 and 14 hours after being wounded) apparently of lung collapse. My note is a follows:—

> The lungs are extremely small, only filling about a quarter of the pleural sacs. They are blue and solid-looking. Pieces of the lower lobes sink in water, but the upper lobes are crepitant. There is no evidence of any bronchial obstruction; the bronchi do not contain blood or any excess of secretion.

Two of the most marked examples of complete pulmonary deflation which I have seen occurred in (1) a soldier shot through the upper part of the left shoulder—lung and pleura uninjured; (2) a girl of 18 who had a hemithyroidectomy under local anæsthesia. Neither of these cases showed cough or expectoration at any time.

Plugging of a bronchus is then an inadequate explanation of post-operative or traumatic collapse of the lungs because it fails to explain: (1) the common bilateral and occasional extensive unilateral deflation; (2) the gradual extension of deflation to the upper lobe of the affected lung; (3) the presence of bronchial breath sounds and increased vocal resonance in the affected lung.

As a result of my experience of examination of hundreds of men with thoracic wounds during the late war, examinations which were clinical, X ray, visual at the time of operation, and, in a number of cases, post mortem; also of the examination of a considerable number of cases of lung complications following operation since the war, I suggest that massive collapse of the lung can only be explained adequately on the following theory.

1. That as a result of a stimulus applied to the body somewhere between the hyoid and the pubes (these are the limits within which in my personal experience injuries have been followed by massive collapse) a reflex constriction of bronchioles is set up.

2. That normally this reflex affects both lungs equally, and results in a decrease in the lung volume with raising of the diaphragm on both sides, and an increase in the negativity of intrapleural pressure. This condition was well seen and was very common in the wounded soldiers in France. In men who had small pleural effusions as the result of a thoracic wound the intrapleural pressure was more negative than normal in spite of the effusion, and the removal of even a few ounces of fluid during the first 48 hours after the injury was likely to be followed by cyanosis, dyspnœa, and marked thoracic pain.

3. In some cases the reflex affects only one lung, not necessarily on the side of the injury, and massive collapse results. It may be that normally the whole bronchial tree dilates slightly during inspiration and again during expiration. Failure to dilate during inspiration with normal dilatation during expiration would lead to pulmonary deflation, and if the abnormality were unilateral to marked collapse.

If we suppose that a reversal of this supposed normal mechanism is possible, so that a normal inspiratory dilatation is converted into an inspiratory constriction of bronchi while the expiratory mechanism remains normal, a far greater degree of deflation is possible. A reversal of the conditions following an injury—that is, a reflex constriction of the bronchi during expiration with normal dilatation during inspiration—may explain the phenomena of asthma, in which expiration is longer than inspiration, and lung overdistension is found.

There are many data in experimental physiology which confirm the presence and action of both dilator and constrictor muscles in the bronchi, and the condition of the lungs in guinea-pigs killed by anaphylactic shock strongly suggests the reflex constriction of bronchi. But the importance of lung collapse lies in (1) its comparative frequency after operations of the upper abdomen, (2) its liability to be the starting-point of pneumonia, (3) the means to be taken to prevent it, (4) treatment. For prevention I believe that combined regional and general anæsthesia should be most effectual.

For treatment in the most marked cases I believe that the best procedure is to introduce a small quantity of air into the pleura on the side of the collapse. This allows the diaphragm to move normally, restores the mediastinum to its median position, and relieves distress—I am, Sir, yours faithfully,

K. DOUGLAS WILKINSON.

Birmingham, July 25th, 1928.

To the Editor of THE LANCET.

SIR,—In THE LANCET of July 21st Dr. Boland and Dr. Sheret advise post-operative postural drainage of the bronchial tree, as a prophylactic of massive collapse, in other words, removal of the secretions when formed. May I suggest that a better method, and one more truly prophylactic, is to prevent the formation of the secretions? In a fairly long experience, extending over many hundreds of abdominal operations, I cannot recall a single instance in which any kind of lung complication occurred, in any case in which the preoperative condition of the lungs was normal and the peritoneal cavity not infected. Instead of the usual preoperative hypodermic injection of atropine gr. $\frac{1}{100}$ with morphia gr. $\frac{1}{6}$ to $\frac{1}{4}$, the patient (adult) is given, half an hour before the operation, an injection of atropine gr. $\frac{1}{50}$ without morphia. This makes the patient so dry that, when he reaches the theatre, he can scarcely smack his lips. This dried-up condition usually persists throughout the operation and for some hours afterwards. Very exceptionally, and only if the patient is secreting profusely, atropine gr. $\frac{1}{50}$ is repeated, either at the end of the operation or after return to the ward. Nearly every case was anæsthetised with ether and was nursed, after operation, in the Fowler position.

I am, Sir, yours faithfully,

Plymouth, July 28th. C. HAMILTON WHITEFORD.

SMOOTH AND ROUGH VARIANTS OF BACTERIA.

To the Editor of THE LANCET.

SIR,—In a special article on this subject appearing in your issue of July 7th (p. 31), it is pointed out that many bacteriologists now recognise that there are wide adaptive fluctuations within the "species," or races, of many bacteria. Later on, however, the writer remarks that the observations of Todd [1] and Cowan [2] are inconsistent, by which I presume he means that both these authors cannot be right because the former found that the rough colonies of streptococci were more virulent than the smooth, whereas the latter found that, as in most other bacterial races which exhibit this phenomenon, the smooth streptococci were relatively more virulent than the rough. Since this is the second time within a week that I have seen the same criticism of Todd and Cowan's results, I thought that a note on one experience at Greenwich might be of general interest.

If S and R are used merely as convenient terms to denote colony appearance without any implication of antigenic structure, then diphtheria bacilli (*Corynebacterium diphtheriæ*) show well-marked rough and smooth varieties when grown on certain culture media. During the years 1922 to 1924 I collected over 100 strains of *C. diphtheriæ*. The chances among this series that an R or S strain would be toxigenic or not were about equal. There was no correlation whatever between the two pairs of characters, R and S, and virulence and avirulence. During 1927 and 1928 nearly 200 strains of *C. diphtheriæ* were isolated from the same school and were examined for R and S qualities and toxigenicity by my co-worker, Surgeon-Commander Parker.[3] The R strains were all avirulent, without any exception, the S strains only produced five avirulent cultures. In this series, therefore, R was always correlated with lack of virulence while S forms were almost invariably virulent to guinea-pigs. I think this evidence, in the lack of any further information, would have been considered good enough by many workers to conclude that the rough variants of *C. diphtheriæ* were always atoxic. The evidence might have led me into such a mistake, but for my past experience and the fact that Parker examined a further 50 strains of *C. diphtheriæ* collected from the environment outside the school. This last series of cultures showed no significant agreement between these characters, the R and S varieties containing both virulent and avirulent strains. These investigations show that, in as distinct a "species" of bacterium as it is practicable to define, two characters could at one time be completely correlated, while in *the same place* at another time the same characters would show no significant correlation. Similarly in one environment, correlation was complete while at *the same time* in a different environment there was no agreement between the same sets of character.

The variability of bacteria is of such fundamental importance in medicine that two further recent observations bearing on this subject are worth noting. Whittle,[4] in a recent paper, makes a praiseworthy attempt to discover a reliable method of distinguishing pneumococci from streptococci. After confessing there are certain discrepancies between his results and that of other workers in the same field, he found bile solubility to be the most reliable criterion by which to recognise a pneumococcus. But after finishing his paper he had the bad luck to find a completely bile-insoluble Type I. pneumococcus which had to be put in a footnote. By a striking coincidence in the same number of the journal which contained the previous reference, Griffith[5] describes a fully virulent R variety of pneumococcus, the only exception he had found in his extensive experience, to the rule that R strains of pneumococci are relatively avirulent to mice when compared with S. Here were two "laws" which seemed inviolate until the exceptions turned up. After our experiences at Greenwich it is conceivable if Whittle or Griffith were to repeat their work in a different country or in 10 to 50 years' time the exception might have become the rule and the rule the exception! Hence there is no necessity to consider such observations as those of Todd and Cowan to be mutually incompatible, especially as these investigators only used a very small number of strains of streptococci in their experiments.

The very fact that there are so many apparent inconsistencies in bacteriological literature would indicate that incongruities are just as often due to bacterial variability, as to errors or differences in technique which is the explanation some bacteriologists still seem to prefer. The bacteria as a group are the most plastic of living organisms, and the different races fluctuate round a conventional specific type. It is one of the most important and difficult tasks of modern bacteriology to define the limits, and estimate the rapidity, of these adaptive fluctuations and to try to discover the environmental stimuli which produce them. Griffith's work, just referred to, is a brilliantly original attempt to do this in the case of pneumococcal types, whether his results are ever confirmed or not. We cannot be reminded too frequently that the "species concept" applied to bacteria is far less definite than when applied to the sexual metazoa. As long ago as 1912 Minchin[6] was uncertain if "species," in the strict biological meaning, occurred among the bacteria at all. Although I would not go as far as that, yet these doubts of an eminent worker in pure biology are a salutary subject for the worker in applied medical biology to ponder over.

I am, Sir, yours faithfully,

SHELDON F. DUDLEY.

Royal Naval College, Greenwich, July 26th, 1928.

CANCER AND DIET.

To the Editor of THE LANCET.

SIR,—On p. 192 of your last issue a speaker at the recent Cancer Conference is reported as saying that "a campaign had been going on amongst the medical profession that certain forms of food produced cancer. An eminent surgeon was even devoting his life to persuading the public that cancer was due to eating meat." As chairman of the Food Committee of the New Health Society and therefore closely connected with its dietetic propaganda, may I state that no such absurd statement has ever been issued by the Society or by its president. The ultimate damage that may accrue from long continued malnutrition and other results of a faulty diet may, in the opinion of some of us, help to explain the cancer problem. This is a theory that the public, at any rate, will be well advised to ponder and act upon.

I am, Sir, yours faithfully,

S. HENNING BELFRAGE.

New Health Society, London, July 31st, 1928.

THE MEDICAL DIRECTORY.

To the Editor of THE LANCET.

SIR,—The annual circular has been posted to each member of the medical profession. If the form has not been received, a duplicate will be sent on request. We shall be grateful for the return of the forms by an early post.—We are, Sir, yours faithfully,

J. AND A. CHURCHILL.

40, Gloucester-place, Portman-square, W. 1,

Obituary.

SIR ARTHUR CHANCE, F.R.C.S. & P. IREL., HON. F.R.C.S. EDIN.,

PAST PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS IN IRELAND.

WE regret to announce the death of Sir Arthur Chance, which occurred at his residence, Merrion-square, Dublin, on July 26th, after a long illness, at the age of 69 years. He had been for many years one of the most prominent members of the profession in Ireland and his death will be regretted by a large circle of patients and friends.

SIR ARTHUR CHANCE.

Photo by Lafayette.

Born in 1859, son of Albert Chance, of Dublin, he received his education in Dublin and obtained diplomas from the two Royal Colleges in 1880, and at once devoted himself to surgery. Whilst a very young man he was appointed surgeon to Jervis-street Hospital, and a few years later moved to the Mater Misericordiæ Hospital, with which he remained connected for the rest of his life. He took an active part in the work of the Council of the Royal College of Surgeons, of which College he was elected President in 1903. For many years past he has represented that body on the General Medical Council and last year was nominated as its representative on the Medical Registration Council of the Irish Free State, a post which, however, he had speedily to resign on account of ill-health. From 1917 to 1920 he was Inspector of Military Surgical Hospitals in Ireland, with the rank of colonel in the Army Medical Service. He filled a term as President of the Royal Academy of Medicine in Ireland, and was surgeon to more than one Viceroy of Ireland, so that when in 1905 he received the honour of knighthood the distinction had been anticipated for him by all who knew him. There were few public professional activities in Ireland in which he did not take an active share. Specially interested in education, he gave very useful service to the General Medical Council, while he was determinedly opposed to any change in the system of medical registration after the establishment of the Irish Free State.

Chance was a man of great versatility and quickness of intellect, who would have been successful in any profession he might have chosen to adopt. His prudent leadership and shrewd judgment will long be missed, and he will be remembered as having played an important part in Irish affairs at a time of special difficulty.

He married, first, Martha, daughter of Daniel Rooney of Belfast, and secondly, Eileen, daughter of William Murphy, of Dartry, who survives him with eight sons and five daughters. Three of his sons are members of the medical profession, one, Mr. Arthur Chance, being surgeon to Dr. Steevens' Hospital, Dublin.

Medical News.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—Diplomas of L.R.C.P. and M.R.C.S. have been conferred upon 167 candidates (136 men and 31 women) who have passed the Final Examination in Medicine, Surgery, and Midwifery of the Conjoint Board, and have complied with the by-laws of the Colleges. The following are the names and medical schools of the successful candidates :—

G. Allen, Birmingham and London ; J. M. Anderson, Durham and Charing Cross ; W. R. Ashby, Cambridge and St. Bart.'s ; Julia C. H. Avery, St. Mary's ; Gertrude C. Banks, Royal Free ; S. Behrman, St. Bart.'s ; W. A. G. Bell, Cambridge and St. Thomas's ; A. Bennett, St. Bart.'s ; Mary Berkeley, Royal Free ; T. H. Berrill, Bristol ; S. P. Bhatia, Bombay and St. Thomas's ; C. H. Birt, Birmingham ; F. A. Blackwood, St. Thomas's ; Kathleen L. Bland and J. R. Bond, Univ. College ; V. G. Morgaonkar, Bombay and London ; N. J. Boulton and R. V. Bradlaw, Guy's ; J. V. Broad, Cambridge and St. George's ; Nellie Brown, Westminster ; E. C. B. Butler, London ; Beatrice A. Butterworth, Royal Free ; E. N. Callum, London ; Catherine F. Cameron, Cambridge and Royal Free ; L. A. Canaan, Yale and London ; Mavis H. D. Carr, Cambridge and Royal Free ; T. H. Carr and B. R. Caygill, Leeds ; Muriel G. E. Clark, Charing Cross ; W. A. Clements, Sheffield ; Nellie Clifton, Royal Free ; Lilian M. C. Clopet, Cardiff ; Dorothy M. Conyers, Royal Free ; T. M. Corcoran, Univ. College ; O. J. C. Cotton, Cambridge and St. Thomas's ; E. Courtin, St. Thomas's ; J. H. Crawford, Cambridge and St. Mary's ; A. T. Croucher, St. Mary's ; A. M. Cunningham, Cambridge and Univ. College ; D. W. Currie, Leeds ; T. Dagger, Liverpool ; A. Danin, Guy's ; H. W. Daukes, St. Thomas's ; W. P. M. Davidson, St. Bart.'s ; E. L. F. De Mel, Ceylon ; W. F. de Villiers, Cape and London ; P. Dickman, Cape and Charing Cross ; C. J. V. Dobbin, Guy's ; G. H. Dobney, Middlesex ; J. F. Duesbury, Birmingham ; J. W. Ellis, Guy's ; R. C. S. Evans, Cardiff ; A. C. Fisher and Cecilia F. Fox, Bristol ; P. H. Fox Cambridge and St. Bart.'s ; E. Fulford, Guy's ; G. H. Garfield, Cardiff ; R. J. S. Garrow, St. Thomas's and Leeds ; F. W. Gilbert, Guy's ; Agnes G. Gillespie, Liverpool ; Y. Gimpelson, Royal Free and St. Mary's ; L. Godlove, Leeds ; S. Goldman and J. P. Gubbins, London ; J. C. Heather, Guy's ; Kathleen M. Henderson, Laurel K. Heny, Helen M. Herbert, and Alice D. M. Hodge, Royal Free ; F. E. G. Hopkins, Cambridge and Guy's ; D. R. House, Bristol ; I. M. Hughes, Manchester ; E. A. Hunter, London ; M. Jafar, Punjab ; M. K. Jilani, Lahore and Liverpool ; A. W. Johns, London ; S. Kaul, Punjab and St. Bart.'s ; G. H. Kennett, Sydney ; B. Kettle, St. Bart.'s ; G. G. King, Madras and St. Mary's ; M. L. Kreitmayer, St. Bart.'s ; Nellie I. Lanckenau, Royal Free and Univ. Coll. ; Kenneth E. Lane, Guy's ; T. C. Larkworthy, Cambridge and St. George's ; E. G. Laurence, St. Bart.'s ; R. R. Leaning, St. Mary's ; J. C. Leigh, Leeds ; G. Leighton, Birmingham ; G. E. Lewis, Cambridge and London ; I. B. Limbery, St. Thomas's ; Kathleen M. MacLaren, Westminster ; G. C. C. MacVicker, Cambridge and St. Bart.'s ; M. J. Malley, St. Bart.'s ; F. B. Mallinson, St. George's ; H. M. Mikhail, Univ. College ; Hermia M. Mills, Royal Free ; L. Milner, S. Africa and Guy's ; W. E. S. Moreton, Charing Cross ; R. H. Morley, Leeds ; I. Morris, Univ. College ; L. H. Morris, Cambridge and London ; O. N. Morris, King's College ; J. E. Morton, Guy's ; Millicent Moseley, Birmingham ; J. H. Moynihan, Charing Cross ; Bhavani Natarajan, Bombay ; L. A. Newton, St. Bart.'s ; H. G. Nimbalker, Bombay and Middlesex ; G. P. Nixon, St. Bart.'s ; G. W. Oliphant, Guy's ; E. G. M. Palser, Univ. College ; A. W. Patton, St. Bart.'s ; Margaret E. Peaker, King's College ; M. G. Pearson, Oxford and Westminster ; A. L. P. Peeney, Manchester ; R. L. P. Peregrine, Oxford and Guy's ; F. Phillips, Adelaide and London ; J. A. Pocock, Cambridge and Univ. College ; H. G. Pritchard, Oxford and Charing Cross ; N. L. Probert, Cardiff and Middlesex ; A. Rabinowitz, Berlin and Middlesex ; R. H. Raine, Durham ; R. J. H. Raines, Leeds ; E. A. P. S. Rawlings, Charing Cross ; R. G. E. Richmond, St. Thomas's ; D. T. Robinson, Manchester ; J. B. Robinson and W. P. Roe, Guy's ; M. V. Samuel, Adelaide and London ; Eluned Saunders, Cardiff and Westminster ; Christine F. T. Saville, Univ. College ; E. H. Sears, Guy's ; H. M. Sein, Calcutta and Guy's ; H. Selby-Brown, Guy's ; H. T. Simmons, Manchester ; W. H. Simonds, Cambridge and St. Thomas's ; D. Sivasubrahmaniam, Madras and London ; Constance B. Smith, King's College ; Edith J. L. Smith, Royal Free ; Elizabeth S. Smith, Birmingham ; E. H. Spickett, St. Bart.'s and Cardiff ; T. T. Stamm, Guy's ; D. M. Stern, Cambridge and London ; R. Ström-Olsen, Cardiff ; A. B. Sullivan, Sydney and London ; A. B. Taylor, Birmingham ; J. G. Thwaites, St. Thomas's ; B. Timothy, Madras and London ; W. E. Tucker, Cambridge and St. George's ; G. N. Unnithan, Madras and Univ. College ; B. T. Utley, St. George's ; L. E. Vine, Bristol ; F. H. Ward, Cambridge and St. Bart.'s ; D. K. Weston, Guy's ; D. B. J. Wijeyesekera, Ceylon and King's College ; P. Wiles, Middlesex ; Gladys E. Wilkinson, Manchester ; G. G. Willcox, Cambridge and St. Thomas's ; Enid M. Williams, Cardiff ; L. D. Williams, Cardiff and Guy's ; W. A. Wilson, Univ. College ; E. W. Winch, Cambridge and St. George's ; H. S. H. Wood, Middlesex ; J. L. M. Wood, Sheffield ; Elsie E. Wright, Royal Free and St. Mary's ; T. C. Yip, St. Bart.'s ; and H. D. R. Zscherpel, Madras and St. Bart.'s.

repeated, either at the end of the operation or after return to the ward. Nearly every case was anæsthetised with ether and was nursed, after operation, in the Fowler position.

I am, Sir, yours faithfully,

Plymouth, July 28th. C. HAMILTON WHITEFORD.

SMOOTH AND ROUGH VARIANTS OF BACTERIA.

To the Editor of THE LANCET.

SIR,—In a special article on this subject appearing in your issue of July 7th (p. 31), it is pointed out that many bacteriologists now recognise that there are wide adaptive fluctuations within the "species," or races, of many bacteria. Later on, however, the writer remarks that the observations of Todd [1] and Cowan [2] are inconsistent, by which I presume he means that both these authors cannot be right because the former found that the rough colonies of streptococci were more virulent than the smooth, whereas the latter found that, as in most other bacterial races which exhibit this phenomenon, the smooth streptococci were relatively more virulent than the rough. Since this is the second time within a week that I have seen the same criticism of Todd and Cowan's results, I thought that a note on one experience at Greenwich might be of general interest.

If S and R are used merely as convenient terms to denote colony appearance without any implication of antigenic structure, then diphtheria bacilli (*Corynebacterium diphtheriæ*) show well-marked rough and smooth varieties when grown on certain culture media. During the years 1922 to 1924 I collected over 100 strains of *C. diphtheriæ*. The chances among this series that an R or S strain would be toxigenic or not were about equal. There was no correlation whatever between the two pairs of characters, R and S, and virulence and avirulence. During 1927 and 1928 nearly 200 strains of *C. diphtheriæ* were isolated from the same school and were examined for R and S qualities and toxigenicity by my co-worker, Surgeon-Commander Parker.[3] The R strains were all avirulent, without any exception, the S strains only produced five avirulent cultures. In this series, therefore, R was always correlated with lack of virulence while S forms were almost invariably virulent to guinea-pigs. I think this evidence, in the lack of any further information, would have been considered good enough by many workers to conclude that the rough variants of *C. diphtheriæ* were always atoxic. The evidence might have led me into such a mistake, but for my past experience and the fact that Parker examined a further 50 strains of *C. diphtheriæ* collected from the environment outside the school. This last series of cultures showed no significant agreement between these characters, the R and S varieties containing both virulent and avirulent strains. These investigations show that, in as distinct a "species" of bacterium as it is practicable to define, two characters could at one time be completely correlated, while in *the same place* at another time the same characters would show no significant correlation. Similarly in one environment, correlation was complete while at *the same time* in *a different environment* there was no agreement between the same sets of character.

The variability of bacteria is of such fundamental importance in medicine that two further recent observations bearing on this subject are worth noting. Whittle,[4] in a recent paper, makes a praiseworthy attempt to discover a reliable method of distinguishing pneumococci from streptococci. After confessing there are certain discrepancies between his results and that of other workers in the same field, he found bile solubility to be the most reliable criterion by which to recognise a pneumococcus. But after finishing his paper he had the bad luck to find a completely bile-insoluble Type I. pneumococcus which had to be put in a footnote. By a striking coincidence in the same number of the journal which contained the previous reference, Griffith[5] describes a fully virulent R variety of pneumococcus, the only exception he had found in his extensive experience, to the rule that R strains of pneumococci are relatively avirulent to mice when compared with S. Here were two "laws" which seemed inviolate until the exceptions turned up. After our experiences at Greenwich it is conceivable if Whittle or Griffith were to repeat their work in a different country or in 10 to 50 years' time the exception might have become the rule and the rule the exception! Hence there is no necessity to consider such observations as those of Todd and Cowan to be mutually incompatible, especially as these investigators only used a very small number of strains of streptococci in their experiments.

The very fact that there are so many apparent inconsistencies in bacteriological literature would indicate that incongruities are just as often due to bacterial variability, as to errors or differences in technique which is the explanation some bacteriologists still seem to prefer. The bacteria as a group are the most plastic of living organisms, and the different races fluctuate round a conventional specific type. It is one of the most important and difficult tasks of modern bacteriology to define the limits, and estimate the rapidity, of these adaptive fluctuations and to try to discover the environmental stimuli which produce them. Griffith's work, just referred to, is a brilliantly original attempt to do this in the case of pneumococcal types, whether his results are ever confirmed or not. We cannot be reminded too frequently that the "species concept" applied to bacteria is far less definite than when applied to the sexual metazoa. As long ago as 1912 Minchin [6] was uncertain if "species," in the strict biological meaning, occurred among the bacteria at all. Although I would not go as far as that, yet these doubts of an eminent worker in pure biology are a salutary subject for the worker in applied medical biology to ponder over.

I am, Sir, yours faithfully,

SHELDON F. DUDLEY.

Royal Naval College, Greenwich, July 26th, 1928.

CANCER AND DIET.

To the Editor of THE LANCET.

SIR,—On p. 192 of your last issue a speaker at the recent Cancer Conference is reported as saying that "a campaign had been going on amongst the medical profession that certain forms of food produced cancer. An eminent surgeon was even devoting his life to persuading the public that cancer was due to eating meat." As chairman of the Food Committee of the New Health Society and therefore closely connected with its dietetic propaganda, may I state that no such absurd statement has ever been issued by the Society or by its president. The ultimate damage that may accrue from long continued malnutrition and other results of a faulty diet may, in the opinion of some of us, help to explain the cancer problem. This is a theory that the public, at any rate, will be well advised to ponder and act upon.

I am, Sir, yours faithfully,

S. HENNING BELFRAGE.

New Health Society, London, July 31st, 1928.

THE MEDICAL DIRECTORY.

To the Editor of THE LANCET.

SIR,—The annual circular has been posted to each member of the medical profession. If the form has not been received, a duplicate will be sent on request. We shall be grateful for the return of the forms by an early post.—We are, Sir, yours faithfully,

J. AND A. CHURCHILL.

40, Gloucester-place, Portman-square, W. 1,
July 26th, 1928.

in Orthopædic Surgery: Esmé M. Gilroy. Wellcome Medals and Prizes in the History of Medicine: Gold Medal, W. A. Bain; Silver Medal, J. A. P. Cameron. Cunningham Memorial Medal and Prize in Anatomy: T. H. Brown. Whiteside Bruce Bursary: J. A. Baty.

Society of Apothecaries of London.—At recent examinations the following candidates passed in the subjects indicated:—

Surgery.—K. E. Clarke, Charing Cross Hosp.; K. G. Milad, St. Mary's Hosp.; and H. Tenenbaum, Nancy and London Hosp.

Medicine.—M. K. Bryce, London Hosp.; J. P. Collinson, Sheffield and London Hosp.; N. Das, London Hosp.; W. B. Hallums, St. Mary's Hosp.; A. H. Hennessey, Adelaide and London Hosp.; E. P. Johnson, Manchester; E. A. Lipkin, Liverpool; and H. S. Marks, Guy's Hosp.

Forensic Medicine.—T. A. Barnabas, Bristol; P. C. Basu, Calcutta; H. C. Clifford-Smith, Charing Cross Hosp.; J. P. Collinson, Sheffield and London Hosp.; H. H. Jackson, Manchester and Charing Cross Hosp.; E. P. Johnson, Manchester; A. A. Leibovitch, Kharkoff and London Hosp.; T. A. P. Proctor, Birmingham; and H. Tenenbaum, Nancy and London Hosp.

Midwifery.—T. A. Barnabas, Bristol; P. C. Basu, Calcutta; J. S. B. Bray, Cambridge and St. Bart.'s Hosp.; A. R. D'Abreu, Leeds; H. W. E. Dickey, Manchester; N. H. Kettlewell, Middlesex Hosp. and Bristol; and S. M. Rahman, Calcutta and Middlesex Hosp.

The Diploma of the Society was granted to the following candidates, entitling them to practise medicine, surgery, and midwifery: P. C. Basu, M. K. Bryce, H. E. Clarke, W. B. Hallums, and H. S. Marks.

University of Belfast.—Dr. A. M. Drennan has been appointed to the chair of pathology in the University. A graduate of Edinburgh, Prof. Drennan, at present occupies the chair of clinical pathology in the University of Otago, New Zealand.

Course of Instruction for D.P.H.—A three months' course of lectures and demonstrations on clinical practice and in hospital administration will be given at the North-Eastern Hospital, St. Ann's-road, Tottenham, London, N., by Dr. F. H. Thomson, the medical superintendent, on Mondays and Wednesdays, at 4.45 P.M., and alternate Saturdays at 11 A.M., beginning on Oct. 1st. Further information may be had from the clerk to the Metropolitan Asylums Board, Victoria Embankment, E.C. 4.

The late Mr. Charles Curd.—The death occurred on July 28th of Mr. Charles Curd in his seventy-third year. A native of Bath, he received his medical education at Charing Cross Hospital, qualified as L.S.A. in 1878 and M.R.C.S. in 1879, and held a house appointment at the hospital. After practice at Amersham and Liskeard he returned to Bath, where he was for many years closely identified with the work of the Royal United Hospital, being chairman of the Board of Management in 1925 and a trustee at the time or his death. During the war he rendered excellent service at the Bath War Hospital. A prominent Freemason, he devoted much of his time to local affairs, and for some time represented Lansdown Ward on the Board of Guardians.

Animal Diseases Research Association.—A donation of £10,000 has been given anonymously to this association, whose headquarters are at Aberdeen, in order to strengthen and increase the research staff.

Secretaryship of St. Thomas's Hospital.—A presentation on behalf of the governors and medical staff of St. Thomas's Hospital, London, has been made to Mr. G. Q. Roberts, C.B.E., who is now retiring from the position of secretary and receiver, which he has held for the last 25 years. Mr. Roberts's successor will be Lieut.-Colonel A. P. B. Irwin, D.S.O., who has been assistant secretary since 1922.

The late Dr. G. O. McKane.—Dr. George Oliphant McKane, who died at Cleethorpes on July 26th in his eighty-first year, had spent nearly half a century in medical practice. He gained the Scottish triple qualification in 1875, and retired only three or four years ago. The last 20 years of his active life were lived at Waltham, near Grimsby, where he carried on a large country practice. He was also medical officer of health to the Grimsby Rural District Council, and poor-law medical officer and public vaccinator to the fourth district of the Grimsby Union. A man of strong and cheerful personality he had great powers of sympathy, and enjoyed the confidence of his patients to a remarkable degree. Dr. McKane was a native of Hexham, and before studying medicine qualified as a chemist. He was for many years in practice at Byers Green, Co. Durham, and Leeds. His two sons are members of the medical profession.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Bills Advanced.

In the House of Lords on Friday, July 27th, the Reorganisation of Offices (Scotland) Bill was read the third time. In the House of Commons the Food and Drugs (Adulteration) Bill was read the third time.

HOUSE OF COMMONS.

Wednesday, July 25th.

Ex-Service Man and Sleepy Sickness.

Sir Henry Cowan asked the Secretary of State for War whether his attention has been called to the case of Alfred Lines (whose blue medical sheet was endorsed Fit for service in any part of the world), who joined the Middlesex Regiment on June 4th, 1926, served with the Shanghai defence force in China until afflicted with sleepy sickness, returned to England and was discharged from Netley Hospital as physically unfit for any form of military service on Nov. 11th, 1927, with a sum of £1, and who, after waiting for his official discharge papers, received a communication from Chelsea Hospital, dated Dec. 5th, 1927, stating that he was not entitled to any discharge pension and offering him a gratuity of £6 only, less deduction of any advances that had been made to him; and whether, having regard to the fact that his panel doctor had certified that Lines would never be able to work again and that the symptoms of the disease which necessitated his discharge from the Army first appeared during his military service with the Shanghai defence force, he would consider granting this man some compensation more adequate than the amount of 7s. 9*d.* actually paid him as the balance of the gratuity of £6.—Mr. Duff Cooper (Financial Secretary to the War Office) replied: This case has been carefully reviewed at the War Office, and the Army medical authorities are satisfied that the disability was not caused by military service. In the circumstances, Mr. Lines has no claim to compensation, and the small gratuity awarded is the appropriate grant in his case.

Replying to further questions in regard to Mr. Lines's case, Mr. Duff Cooper said the War Office could not allow the principle to be established that anybody who happened to fall ill while on military service should by that fact alone be entitled to some compensation. There was no evidence to show that this man's illness was in any way connected with his being sent abroad. It was not an illness to which soldiers were subject through their being sent abroad.

Health of the Merchant Service.

Dr. Vernon Davies asked the President of the Board of Trade if he would consider the advisability of coöperating with the Minister of Health to issue an annual report on the health of the merchant service, bearing in mind that the seaman's mortality from disease exceeded the average by 48·8 per cent., and his mortality from violence by 4·30 per cent.—Mr. Herbert G. Williams (Parliamentary Secretary to the Board of Trade) replied: My right hon. friend will consult the Minister of Health with regard to the suggested preparation of an annual report on the health of the merchant service, and I will let my hon. friend know the result in due course.

Tuberculosis Mortality-rate.

Sir Robert Thomas asked the Minister of Health whether he was aware that there had been since 1910 little reduction in the tuberculosis mortality-rate for males between the ages of 15 and 25, while for females between these ages the rate had increased; and what measures he proposed to take to improve the position.—Sir Kingsley Wood replied: The answer to the first part of the question is in the affirmative, but the rate for both males and females between these ages appears at the present time to be decreasing. The discrepancy between the rate of decrease in the mortality from tuberculosis in the general population and that in the groups referred by the hon. Member has been under consideration in my department, but my right hon. friend is advised that its causes are obscure. Investigation is proceeding, and the tuberculosis officers of local authorities will be asked to give special attention to the question.

Thursday, July 26th.

Treatment of Casual Paupers.

Mr. Shepherd asked the Minister of Health whether, in view of the number of unemployed men and women now tramping the roads in search of employment, he proposed to revise the regulations concerning their treatment, with special regard to food, sleeping, medical inspection, searching, task work, detention, washing, and method of obtaining

The undermentioned diplomas were conferred (jointly with the Royal College of Surgeons) upon the following candidates:—

DIPLOMA IN OPHTHALMIC MEDICINE AND SURGERY.

C. H. Ackroyd, C. H. Bamford, W. J. Chapman, A. L. El Kirdani, Charlotte E. Fisher, B. B. Ghosh, J. B. Hamilton, R. J. Harley-Mason, D. R. Jadeja, D. Katz, G. L. Khirwadkar, D. G. Kotibhaskar, F. J. Lavery, H. H. Mahmood, T. M. O'Neill, F. W. G. Smith, A. F. Stewart, J. M. Thomson, A. Walbank, and J. Wood.

DIPLOMA IN PUBLIC HEALTH.

D. R. Bernhardt, R. A. D. J. Bernhardt, H. P. Billimoria, H. St. C. Colston, A. C. Counsell, G. I. Davies, C. H. Dhala, M. Farid, F. Harris, G. H. Hayes, Margaret Holdsworth, D. R. Jandial, Iris A. Jenkin-Lloyd, Eva M. Malmberg, S. N. Michaels, Josefine W. Nagel, M. A. Nicholson, F. W. Oldershaw, D. B. Parakh, Jessie L. Robb, Mary Schofield, Beatrice M. Smithies, Josephine I. Terry, D. L. Tucker, and G. R. Waller.

Diplomas in Laryngology and Otology and in Psychological Medicine have been conferred upon candidates whose names appeared in our issue of July 21st (p. 153).

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—At an ordinary meeting of the College held on July 26th, with *Sir John Rose Bradford, the President, in the chair*, the following were elected members:—

Charles N. Armstrong, Ramananda Bandyopadhyay, Philip Bayer, John L. Edwards, Frank R. Fletcher, Robert D. Gillespie, Frank Goldby, Hamilton Hartridge, Thomas R. Hill, Horace Joules, Charles E. Kellett, Robert M. B. Mackenna, Patrick H. O'Donovan, Ian H. K. Stevens, and Arthur S. Wesson.

Licences to practise medicine were conferred on 167 candidates whose names appear above.

Mr. Arthur Sturgess Hollins, M.B. Camb., M.R.C.P., of King's College Hospital, was awarded the Murchison Memorial Scholarship.

The following officers of the College, members of committees, and examiners were elected for the ensuing year:—

Censors.—Lord Dawson of Penn, Dr. J. S. Collier, Dr. A. P. Beddard, and Dr. R. A. Young.

Treasurer.—Dr. S. P. Phillips.

Registrar.—Dr. Raymond Crawfurd.

Harveian Librarian.—Dr. Arnold Chaplin.

Assistant Registrar.—Dr. R. O. Moon.

Library Committee.—Dr. F. Parkes Weber, Dr. H. C. Cameron, Dr. H. R. Spencer, and Dr. C. J. Singer.

Curators of the Museum.—Dr. J. M. Bruce, Dr. C. E. Lakin, Dr. William Hunter, and Dr. J. H. Thursfield.

Finance Committee.—Dr. H. Morley Fletcher, Sir John Broadbent, and Dr. J. H. Thursfield.

Examiners.—Chemistry: Mr. H. W. Cremer and Mr. W. H. Hurtley. Physics: Mr. J. H. Brinkworth and Mr. D. Orson Wood. Practical Pharmacy: Dr. W. J. Adie, Dr. Hugh Gainsborough, Dr. Newman Neild, Dr. V. J. Woolley, and Dr. Orlando Inchley. Physiology: Dr. B. J. Collingwood and Dr. Swale Vincent. Anatomy: Dr. G. Elliot Smith. Pathology: Sir Frederick Andrewes and Dr. Charles Bolton. Medical Anatomy and Principles and Practice of Medicine: Sir Percival Hartley, Dr. A. G. Phear, Dr. Herbert French, Dr. A. E. Russell, Dr. Cecil Wall, Dr. J. A. Nixon, Dr. Frederick Langmead, Dr. C. E. Lakin, Dr. D. H. de Souza, and Dr. F. M. R. Walshe. Midwifery and Diseases Peculiar to Women: Dr. Cuthbert Lockyer, Dr. Eardley Holland, Dr. Malcolm Donaldson, F.R.C.S., Dr. William Gilliatt, and Dr. Stanley Dodd. Public Health: Part I., Dr. J. H. Ryffel; Part II., Dr. Charles Porter. Tropical Medicine: Dr. J. C. G. Ledingham and Dr. H. H. Scott. Ophthalmic Medicine and Surgery: Dr. Grainger Stewart. Psychological Medicine: Part I., Dr. Edward Mapother; Part II., Dr. J. Porter Phillips and Dr. Bernard Hart. Laryngology and Otology: Dr. D. R. Paterson.

Sir Humphry Rolleston was re-elected as representative on the Executive Committee of the Imperial Cancer Research Fund.

Sir Wilmot Herringham was appointed to deliver the Harveian Oration, and Dr. J. A. Arkwright, F.R.S., the Bradshaw Lecture in 1929. The following further appointments were announced: Dr. G. F. Still as Fitzpatrick Lecturer for 1929; Dr. R. A. Young as Lumleian Lecturer for 1929; Dr. E. B. Verney as Goulstonian Lecturer for 1929; Dr. F. M. R. Walshe as Oliver-Sharpey Lecturer for 1929; The Rt. Hon. H. A. L. Fisher as Lloyd Roberts Lecturer for 1929; and Sir Charles Martin as Croonian Lecturer for 1930.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—The following candidates for the Triple Qualification have been approved and have been admitted as Licentiates:—

FINAL EXAMINATION.

Betty C. Hamilton, E. A. Downes, John Campbell, D. A. Herd, A. J. A. Gray, Oscher Stern, J. L. Dudgeon, C. V. Salisbury, S. K. *Pillai*, M. J. S. *Pillai*, A. M. D'Cotta, Maud Heaton, H. S. Lawrence, A. F. B. Mackay, A. El Sayed El Khishin, A. B. Mendis, Robert Rajaretnam Tamber, N. S. Fraser, C. L. X. S. Muttukumaru, I. M. Chisholm, A. M. Fraser, David Bendel, Barney Schulman, F. E. Ll. Stewart, Harry Lazarus, H. M. C. de Silva, B. S. Swani, E. H. B. Gooch, W. D. Alvis, Aaron Jacorovitch, R. A. F. M. Saunders, A. J. F. Almeida, F. A. Silva, and J. S. Goonting.

The following have satisfied the examiners in the undermentioned subjects:—

Medicine.—J. T. F. Pearse, J. H. Brush, D. N. Chisholm, H. A. Mohamed, Gerald Kahn, Hope Lazarus, L. O. Abeyaraine, Chrysostom Joseph, Leslie Myers, A. K. M. Attia, S. S. Nagi, and Hyam Saacs.

Surgery.—J. R. Martin, J. T. F. Pearse, Hanna Barsoum, J. H. Brush, C. H. Wilkie, C. Joseph, Leslie Craig, Okunade Ajibade, A. L. Malik-Mansour, A. K. M. Attia, Hugh Craig, and Kandiah Kanagasabapathy.

Midwifery and Gynæcology.—J. R. Martin, F. R. B. H. K[illegible] J[illegible] L[illegible] Brink, and Hyams Saacs.

Medical Jurisprudence and Public Health.—M. C. Smith, W. O. Molander, F. R. B. H. Kennedy, W. P. Kennedy, G. G. Brown, H. G. Somerville, Margaret Leslie, John McConnell, Amin Madwar, Dorothy Williams, R. L. Allan, L. C. Leslie, Harry Michaelson, Agnes F. Millar, R. T. Amour, J. E. Morrison, J. W. Gregory, and W. V. Anderson.

UNIVERSITY OF EDINBURGH.—At a graduation ceremonial on July 18th the following degrees were conferred:—

M.D.

†Harry Bedingfield, ‡J. C. R. Buchanan, J. J. B. Edmond, F. W. Gavin, ‡C. G. Gooding, James Gray, ‡Muriel G. Henderson, ‡J. C. Hodgson, J. C. Macgown, J. D. P. M'Latchie, ‡G. W. Milroy, *J. W. T. Patterson, N. H. Smith, and A. J. Wilson.

Paterson (*equal*). *Pattison* Prize in Clinical Surgery: I. G. W. Hill. Sir Robert Jones Prize in Orthopædic Surgery: Esmé M. Gilroy. Wellcome Medals and Prizes in the History of Medicine: Gold Medal, W. A. Bain; Silver Medal, J. A. P. Cameron. Cunningham Memorial Medal and Prize in Anatomy: T. H. Brown. Whiteside Bruce Bursary: J. A. Baty.

SOCIETY OF APOTHECARIES OF LONDON.—At recent examinations the following candidates passed in the subjects indicated:—

Surgery.—K. E. Clarke, Charing Cross Hosp.; K. G. Milad, St. Mary's Hosp.; and H. Tenenbaum, Nancy and London Hosp.

Medicine.—M. K. Bryce, London Hosp.; J. P. Collinson, Sheffield and London Hosp.; N. Das, London Hosp.; W. B. Hallums, St. Mary's Hosp.; A. H. Hennessey, Adelaide and London Hosp.; E. P. Johnson, Manchester; E. A. Lipkin, Liverpool; and H. S. Marks, Guy's Hosp.

Forensic Medicine.—T. A. Barnabas, Bristol; P. C. Basu, Calcutta; H. C. Clifford-Smith, Charing Cross Hosp.; J. P. Collinson, Sheffield and London Hosp.; H. H. Jackson, Manchester and Charing Cross Hosp.; E. P. Johnson, Manchester; A. A. Leibovitch, Kharkoff and London Hosp.; T. A. P. Proctor, Birmingham; and H. Tenenbaum, Nancy and London Hosp.

Midwifery.—T. A. Barnabas, Bristol; P. C. Basu, Calcutta; J. S. B. Bray, Cambridge and St. Bart.'s Hosp.; A. R. D'Abreu, Leeds; H. W. E. Dickey, Manchester; N. H. Kettlewell, Middlesex Hosp. and Bristol; and S. M. Rahman, Calcutta and Middlesex Hosp.

The Diploma of the Society was granted to the following candidates, entitling them to practise medicine, surgery, and midwifery: P. C. Basu, M. K. Bryce, H. E. Clarke, W. B. Hallums, and H. S. Marks.

UNIVERSITY OF BELFAST.—Dr. A. M. Drennan has been appointed to the chair of pathology in the University. A graduate of Edinburgh, Prof. Drennan, at present occupies the chair of clinical pathology in the University of Otago, New Zealand.

COURSE OF INSTRUCTION FOR D.P.H.—A three months' course of lectures and demonstrations on clinical practicé and in hospital administration will be given at the North-Eastern Hospital, St. Ann's-road, Tottenham, London, N., by Dr. F. H. Thomson, the medical superintendent, on Mondays and Wednesdays, at 4.45 P.M., and alternate Saturdays at 11 A.M., beginning on Oct. 1st. Further information may be had from the clerk to the Metropolitan Asylums Board, Victoria Embankment, E.C. 4.

THE LATE MR. CHARLES CURD.—The death occurred on July 28th of Mr. Charles Curd in his seventy-third year. A native of Bath, he received his medical education at Charing Cross Hospital, qualified as L.S.A. in 1878 and M.R.C.S. in 1879, and held a house appointment at the hospital. After practice at Amersham and Liskeard he returned to Bath, where he was for many years closely identified with the work of the Royal United Hospital, being chairman of the Board of Management in 1925 and a trustee at the time or his death. During the war he rendered excellent service at the Bath War Hospital. A prominent Freemason, he devoted much of his time to local affairs, and for some time represented Lansdown Ward on the Board of Guardians.

ANIMAL DISEASES RESEARCH ASSOCIATION.—A donation of £10,000 has been given anonymously to this association, whose headquarters are at Aberdeen, in order to strengthen and increase the research staff.

SECRETARYSHIP OF ST. THOMAS'S HOSPITAL.—A presentation on behalf of the governors and medical staff of St. Thomas's Hospital, London, has been made to Mr. G. Q. Roberts, C.B.E., who is now retiring from the position of secretary and receiver, which he has held for the last 25 years. Mr. Roberts's successor will be Lieut.-Colonel A. P. B. Irwin, D.S.O., who has been assistant secretary since 1922.

THE LATE DR. G. O. MCKANE.—Dr. George Oliphant McKane, who died at Cleethorpes on July 26th in his eighty-first year, had spent nearly half a century in medical practice. He gained the Scottish triple qualification in 1875, and retired only three or four years ago. The last 20 years of his active life were lived at Waltham, near Grimsby, where he carried on a large country practice. He was also medical officer of health to the Grimsby Rural District Council, and poor-law medical officer and public vaccinator to the fourth district of the Grimsby Union. A man of strong and cheerful personality he had great powers of sympathy, and enjoyed the confidence of his patients to a remarkable degree. Dr. McKane was a native of Hexham, and before studying medicine qualified as a chemist. He was for many years in practice at Byers Green, Co. Durham, and Leeds. His two sons are members of the medical profession.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Bills Advanced.

IN the House of Lords on Friday, July 27th, the Reorganisation of Offices (Scotland) Bill was read the third time. In the House of Commons the Food and Drugs (Adulteration) Bill was read the third time.

HOUSE OF COMMONS.

WEDNESDAY, JULY 25TH.

Ex-Service Man and Sleepy Sickness.

Sir HENRY COWAN asked the Secretary of State for War whether his attention has been called to the case of Alfred Lines (whose blue medical sheet was endorsed Fit for service in any part of the world), who joined the Middlesex Regiment on June 4th, 1926, served with the Shanghai defence force in China until afflicted with sleepy sickness, returned to England and was discharged from Netley Hospital as physically unfit for any form of military service on Nov. 11th, 1927, with a sum of £1, and who, after waiting for his official discharge papers, received a communication from Chelsea Hospital, dated Dec. 5th, 1927, stating that he was not entitled to any discharge pension and offering him a gratuity of £6 only, less deduction of any advances that had been made to him; and whether, having regard to the fact that his panel doctor had certified that Lines would never be able to work again and that the symptoms of the disease which necessitated his discharge from the Army first appeared during his military servicé with the Shanghai defence force, he would consider granting this man some compensation more adequate than the amount of *7s. 9d.* actually paid him as the balance of the gratuity of £6.—Mr. DUFF COOPER (Financial Secretary to the War Office) replied: This case has been carefully reviewed at the War Office, and the Army medical authorities are satisfied that the disability was not caused by military service. In the circumstances, Mr. Lines has no claim to compensation, and the small gratuity awarded is the appropriate grant in his case.

Replying to further questions in regard to Mr. Lines's case, Mr. Duff Cooper said the War Office could not allow the principle to be established that anybody who happened to fall ill while on military service should by that fact alone be entitled to some compensation. There was no evidence to show that this man's illness was in any way connected with his being sent abroad. It was not an illness to which soldiers were subject through their being sent abroad.

Health of the Merchant Service.

Dr. VERNON DAVIES asked the President of the Board of Trade if he would consider the advisability of coöperating with the Minister of Health to issue an annual report on the health of the merchant service, bearing in mind that the seaman's mortality from disease exceeded the average by 48·8 per cent., and his mortality from violence by 4·30 per cent.—Mr. HERBERT G. WILLIAMS (Parliamentary Secretary to the Board of Trade) replied: My right hon. friend will consult the Minister of Health with regard to the suggested preparation of an annual report on the health of the merchant service, and I will let my hon. friend know the result in due course.

Tuberculosis Mortality-rate.

Sir ROBERT THOMAS asked the Minister of Health whether he was aware that there had been since 1910 little reduction in the tuberculosis mortality-rate for males between the ages of 15 and 25, while for females between these ages the rate had increased; and what measures he proposed to take to improve the position.—Sir KINGSLEY WOOD replied: The answer to the first part of the question is in the affirmative, but the rate for both males and females between these ages appears at the present time to be decreasing. The discrepancy between the rate of decrease in the mortality from tuberculosis in the general population and that in the groups referred by the hon. Member has been under consideration in my department, but my right hon. friend is advised that its causes are obscure. Investigation is proceeding, and the tuberculosis officers of local authorities will be asked to give special attention to the question.

THURSDAY, JULY 26TH.

Treatment of Casual Paupers.

Mr. SHEPHERD asked the Minister of Health whether, in view of the number of unemployed men and women now tramping the roads in search of employment, he proposed to revise the regulations concerning their treatment, with special regard to food, sleeping, medical inspection, searching, task work, detention, washing, and method of obtaining admission.—Mr. CHAMBERLAIN replied : No, Sir. I am not aware of any reason for the revision of the regulations in force, which do, as the hon. Member is aware, make special provision for casuals genuinely in search of employment. I think it is important that there should be general and complete compliance with the regulations, and I am giving my officers further special instructions to impress upon guardians and their staffs the necessity of securing this full compliance in cases in which there is any default.

Shortage of Water in Derbyshire.

Mr. DUNCAN asked the Minister of Health whether he was aware of complaints of the short supply of water for domestic purposes in the parish of South Normanton, in the Blackwell rural district council area, Derbyshire ; whether this shortage covered a period of years ; whether complaints had previously been made to the Ministry of Health ; whether the local authorities had laid any proposals before the Ministry for approval, and whether there was any delay occasioned in his department in this matter ; and whether he was prepared to take immediate action with a view to terminating the present shortage and providing the area with a full supply sufficient for the general health and domestic needs of the inhabitants.—Mr. CHAMBERLAIN replied : The answers to the first four parts of the question are in the affirmative, and to the sixth part in the negative. In reply to the fifth part, an outline of a joint scheme was submitted to me in April, 1927, and provisionally approved in January last, but in the meantime further difficulties have arisen in connexion with the risk of subsidence. In reply to the seventh part of the question, I have directed one of my inspectors to make a local investigation with a view to expediting temporary relief, and I am hoping to receive from the local authorities concerned definite proposals for a permanent scheme on satisfactory lines.

New Cancer Hospital in Manchester.

Sir THOMAS WATTS asked the Minister of Health if his attention had been called to the proposed establishment of a cancer hospital in Palatine-road, Withington, a residential district of Manchester ; and, having regard to the depreciation in the value of property in the district which would result, would he set up an inquiry into the matter.—Mr. CHAMBERLAIN replied : The answer to the first question is in the negative. If, as I assume, the reference is to the establishment of a voluntary hospital, I am not aware that it is open to me to take any action.

Traffic Noises in Urban Streets.

Sir ROBERT THOMAS asked the Home Secretary whether he was aware that there is a growing volume of public protest against the noise of urban streets ; that it was endangering the lives of sick people and undermining the fitness even of those in normal health ; that it interfered with education and lowered the efficiency of business ; that experts estimated that 60 per cent. of the noise was preventable ; and that it would continue to increase unless action was taken ; and whether he would, in conjunction with the Ministers of Health and Transport, make an effort to deal with these conditions.—Sir W. JOYNSON-HICKS replied : I am aware that there is much complaint, and I think with good ground. I have done all in my power to see that the nuisance is abated, so far as this is possible, by police action under existing powers, and I will certainly consult with my right hon. friends as to whether anything further can be done.

Sir R. THOMAS : Is the right hon. gentleman aware that a high medical authority at a meeting of the British Medical Association last week estimated that the loss in efficiency to the nation owing to these noises amounted to no less a sum than £1,000,000 a week ?

Sir W. JOYNSON-HICKS : Yes, I have noticed that.

Lieut.-Commander KENWORTHY : Will the right hon. gentleman consult with the Prime Minister about this in view of the probability that the present laws are insufficient to deal with the growing noises ?

Mr. LANSBURY : Will the right hon. gentleman communicate with the London County Council and ask them to keep the tramway tracks in order and thus prevent the most infernal noises ?

Sir W. JOYNSON-HICKS : I will communicate with the Minister of Transport whose duty it would be, I think, to communicate with the London County Council.

Captain CROOKSHANK : Will the right hon. gentleman look into the practice which obtains in the United States of zoning certain areas where certain noises are prohibited ?

Sir R. THOMAS said that this was a fearfully important question, and he thought that the House ought to get from the Home Secretary something more than they had had. The right hon. gentleman had said that he would consult with his Ministerial colleagues. Could he do so and report to the House before the end of the session ?

Sir W. JOYNSON-HICKS said that he would take the opportunity of discussing the matter with his colleagues, but whether it would be possible to answer a definite question before the end of the session he could not say.

Conjunctivitis in the Artificial Silk Industry.

Mr. KELLY asked the Home Secretary whether reports had been received from his inspectors about the increase in injuries suffered by men and women engaged in the artificial silk industry.—Sir WILLIAM JOYNSON-HICKS replied : I have received reports by the inspectors which I am glad to state show that, except in one works where there has been a large increase in the number of persons employed, the number of cases of conjunctivitis has, during recent months, been decreasing. As the hon. Member knows, this industry is receiving the closest attention both from the staff generally and from the medical inspectors, and much has been, and is being, done to improve the conditions.

Early Treatment of Mental Disease.

Dr. VERNON DAVIES asked the Minister of Health if he was aware that the only hope of reducing the incidence of insanity and improving the recovery-rate was by altering the law so as to allow and encourage the early and skilled treatment of persons mentally ill ; and if he would, at any early date, give this matter his serious consideration and take the necessary action.—Mr. CHAMBERLAIN replied : I should be sorry to think that the *only* hope of reducing the incidence of insanity and improving the recovery-rate lay in the measures which my hon. friend suggests. But I fully realise the great importance of improving the facilities for early mental treatment, and as I have frequently stated, I hope to be able to take the necessary action as soon as it is practicable to introduce legislation.

Regional Medical Officers and Drug Prescriptions.

Mr. SHORT asked the Minister of Health whether any special sum was allocated for the payment of drugs prescribed by panel doctors ; whether he was aware that regional medical officers had recently brought pressure upon panel doctors respecting their prescriptions and thereby limiting their discretion in prescribing medicines for panel patients, and that the East Sussex Insurance Committee, at its meeting on July 3rd, expressed its view that a practitioner should not cease to prescribe drugs which he believed to be reasonably necessary for the adequate treatment of panel patients ; and if he would explain the nature of the instructions given to regional medical officers on this matter.—Mr. CHAMBERLAIN replied : As regards the first part of the question, I would refer the hon. Member to the reply given to a question on April 4th. I am aware of the views expressed by the East Sussex Insurance Committee. The duty of insurance practitioners is to prescribe proper and sufficient medicines, and the purpose of the interviews arranged between certain practitioners and regional medical officers is solely to secure that this duty is performed.

MONDAY, JULY 30TH.

Welsh Board of Health.

Mr. JOHN asked the Minister of Health if the reason for the change in the composition of the promotion board in the office of the Welsh Board of Health was due to the alleged internal difficulties ; and whether he had received complaints with regard to the action of the promotion board in recommending promotions.—Mr. CHAMBERLAIN replied : The answer to both questions is that troubles in regard to promotion have been part of the internal difficulties of the past, and that the change in question seems to me the best way of securing a better position in the future.

Analysts and Food and Drugs Adulteration Bill.

Mr. CECIL WILSON asked the Minister of Health whether, in regard to the Food and Drugs (Adulteration) Bill, any consultation had taken place with the Institute of Chemistry, or the Society of Analysts, or other similar bodies ; and, if not, for what reason.—Mr. CHAMBERLAIN replied : No, Sir. As the object of the Bill is not the amendment but the consolidation of the existing law, its preparation was a purely legal matter, and it was not considered necessary to consult the bodies mentioned. I understand, however, that the Society of Public Analysts communicated with the Joint Committee on Consolidation Bills, and that the Committee considered the Society's views on the Bill.

Sewage Effluvia and Public Health.

Mr. LOOKER asked the Minister of Health whether he was aware that the effluvia coming from the sewage disposal works of the West Kent Sewerage Board constituted a menace to the health of the inhabitants of the parish of West Thurrock : and if he would take steps in the matter.—Mr. CHAMBERLAIN replied : I am not aware that there is any menace to health from this cause. I understand that officials of the District Council and the Sewerage Board have been conferring on the subject and I am ascertaining the position.

TUESDAY, JULY 31ST.

Use of Preservatives in Cream.

Mr. **THOMAS KENNEDY** asked the Secretary of State for Scotland if he had considered any representations made to him by the distributors of fresh cream in Scotland regarding the loss involved in the observance of the regulations prohibiting the use of preservative in cream; if he was aware that large quantities of cream sent daily from the creameries was unfit for use before it reached its destination; that as a consequence tinned foreign cream was rapidly taking the place of home-produced double fresh cream in the Scottish market; that the foreign cream was inferior in food value; that before the passing of the present regulations a harmless and minute quantity of boron preservative was allowed, which was sufficient to keep cream in perfect condition for three days or more; and if he would now consider the desirability of suspending the regulations referred to.

Mr. **WESTWOOD** asked the Secretary of State for Scotland if he had received any communication from the distributors of fresh double cream drawing his attention to the effect of the prohibition of the use of 0·04 per cent. of boron preservative in cream; and, if so, what action, if any, he proposed in the interests of farmers, distributors, and the general public.—Sir J. **GILMOUR** replied: Representations on the various points mentioned in the questions have been received but, for reasons which I have already given, I am not prepared to suspend the operation of the Preservative Regulations in regard to double cream. This matter has been long and carefully considered and the Scottish Board of Health are satisfied that if proper attention is given at all stages to the production of milk and the handling and transit of cream it ought to be possible to market fresh double cream in a sound condition. In regard to the suggestion that the amount of preservative added to double cream before the regulations came into operation was harmless and minute, I would point out that the amount used was 0·4 per cent., and that the Departmental Committee on Preservatives reported against the use of boric acid in foodstuffs in the interests of public health. So far as concerns the interests of farmers, the National Farmers Union of Scotland and the Scottish Agricultural Organisation Society have passed resolutions in favour of the prohibition of preservatives in cream.

Short Measure in the Sale of Milk.

Mr. **LOUGHER** asked the President of the Board of Trade whether, in respect of the sale of milk, he could state the cause of the delay in issuing regulations to enable adequate control to be maintained in connexion with methods of filling milk bottles; and whether he was satisfied that the public were at present adequately guarded against short measure being supplied.

Colonel **ENGLAND** asked the President of the Board of Trade if he was now operating the section of the Weights and Measures Act which prescribed the use of milk bottling and measuring machines; if so, when this section of the Act became operative; and what steps had been taken to carry it out.—Sir P. **CUNLIFFE-LISTER** replied: There is no Act of Parliament which prescribes the use of milk bottling and measuring machines, but draft regulations applying to such machines the general provisions of the Weights and Measures Acts are now under consideration by a small committee representative of local authorities and other interests concerned. I hope to be able to issue the draft shortly for public information. In the meantime the provisions of the Sale of Food Act, 1926, which makes it an offence to give short measure, are available for the protection of the public.

Grants for Supply of Milk and Nourishment.

Mr. **THURTLE** asked the Minister of Health the total amount of economy in Exchequer expenditure he expected to effect by his proposals to local authorities to cut down their grants for the supply of milk and nourishment in connexion with maternity and child welfare work.—Mr. **CHAMBERLAIN** replied: It is estimated that the total amount of the Exchequer grants payable to local authorities in respect of their expenditure for this purpose during the present financial year will be about £12,000 less than would have been the case in normal circumstances.

Sun Helmets for Police Constables.

Lieut.-Commander **KENWORTHY** asked the Secretary of State for the Home Department if he would consider the issue of an approved type of sun helmet, especially to constables employed on traffic control in the middle of the streets during hot weather.—Sir W. **JOYNSON-HICKS** replied: The question has been considered, but our summers are usually so short and changeable that it has not hitherto been thought necessary to provide any special sun or straw helmets. When the weather is hot, orders are given for the removal of chin straps, and if the heat continues the question will be further considered.

Vacancies.

For further information refer to the advertisement columns.

Barry Accident and Surgical Hospital.—H.S. At rate of £200.

Bath, Royal United Hospital.—Asst. H.S. £100. Also H.S. and H.P. Each £120.

Belfast, City and County Borough of.—Med. Supt. O.H., &c. £2000.

Bolton, Townleys Hospital, Farnworth.—Second Asst. M.O. £225.

Bootle, Bootle Borough Hospital, Derby-road.—Sen. M.O. Also 2 Jun. M.O.'s. Each at rate of £150 and £125 respectively.

Brighton, Royal Sussex County Hospital.—H.S. £150.

Bristol Royal Infirmary.—H.P.'s, H.S.'s, also Dental H.S. Each at rate of £80.

Cardiff, Prince of Wales' Hospital.—H.S. £100.

Cardiff, University College.—Lecturer and Demonstrator in Anatomy.

Central London Ophthalmic Hospital, Judd-street, St. Pancras, W.C.—Sen. H.S. £100.

Chester County Mental Hospital.—Fourth Asst. M.O. £350.

City of London Hospital for Diseases of the Heart, &c., Victoria Park, E.—H. P. At rate of £100.

Reading, Royal [illegible] S. £150.

Rotherham, Rothe[illegible]0.

Royal College of [illegible]—Milroy Lecturer.

Tuberculosis Dis[illegible] *Laboratory, 114, New King's-road,* [illegible]—Tuberculosis Officer and Asst. M.O.H. £750.

West Bromwich, West Bromwich and District General Hospital.—Res. H.S., H.S., also Cas. H.S. Each at rate of £200.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Carnwath (Lanarkshire).

Births, Marriages, and Deaths.

BIRTHS.

BAKER.—On July 22nd, at Langton's Meadow, Farnham Common, Bucks, the wife of Ormonde A. Baker, M.B., of a son.

CAIRNS.—On July 29th, at Norfolk-road, N.W., the wife of Hugh Cairns, F.R.C.S., of a daughter.

MARRIAGES.

BREWS—CHURCHILL.—On July 24th, at All Saints', Great Holland, Essex, Richard Allan Brews, M.D., F.R.C.S., to Gwyneth Grace, only child of Rev. J. D. and Mrs. Churchill, late of Little Bentley Rectory, Essex.

KOHNSTAM—DUNN.—On July 28th, at Lewisham, Geoffrey L. S. Kohnstam, M.D., M.R.C.P. Lond., to Helen Lorna Dunn, M.R.C.S. Eng., L.R.C.P. Lond., only daughter of Mr. and Mrs. F. W. Dunn.

MCCULLOCH—WRIGHT.—On July 26th, at St. Ann's Church, Manchester, William Edward McCulloch, M.B., Ch.B., Pathologist, Nigeria (West African Medical Service), to Joan, youngest daughter of the late Ernest Chorley Wright and Mrs. Wright, of Brabyns Cottage, Marple, late of Stretford.

MEEHAN—STRATHDEE.—On July 25th, at St. Sylvester's Church, Elgin, Felix Patrick Meehan, M.B., Ch.B., to Ann Barclay, second daughter of Mr. and Mrs. James Strathdee, "Braehead," Botriphnie, Keith.

DEATHS.

CHANCE.—On July 26th, in Dublin, Sir Arthur Chance, F.R.C.S.I., F.R.C.P.I., F.R.C.S. Edin., in his 70th year.

CURD.—On July 27th, at Forbes Fraser Hospital, after two days' illness, Charles Curd, M.R.C.S., L.S.A., of Gay-street, Bath.

LEES.—On July 22nd, at Breifond, Boyne Park, Tunbridge Wells, Charlie Lees, M.R.C.S., L.R.C.P., L.D.S. Eng., aged 53.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

HERPES ZOSTER AND CHICKEN-POX.

CASES are always being reported in which herpes zoster and chicken-pox appear in the same household, or in which people develop varicella after being in contact with herpes zoster, and vice versa. The isolated examples must now number many hundreds and constitute a formidable obstacle to the dualists who maintain that there is no inherent connexion between the two conditions. J. von Bókay, in 1892, was the first to suggest a common ætiology, and much evidence in its favour has since been adduced. Dr. G. A. Esquier, for instance, has just described a case in which the two conditions appeared simultaneously.[1] The patient was a soldier of 21, who did not report sick until the fourth day of his attack of chicken-pox, when fever and, more particularly, severe pain in his left side, took him to hospital. At that time typical vesicles in all stages of development were found on the scalp and body and—more sparsely—on the face, neck, and buccal mucosa. There were none on the limbs nor on the left side, where the pain was, and on this area typical herpes zoster developed along the seventh intercostal nerve. The zona consisted of vesicles of varying maturity, the youngest being at the end of the nerve, and the oldest near its root. The number of lymphocytes in the cerebro-spinal fluid proved to be 28 per cubic millimetre, and the differential white cell count in the blood showed 42 per cent. of lymphocytes and only 15 per cent. of polymorphonuclear leucocytes. As the crusts fell off, the blood count returned towards normal. Dr. Esquier explains this case by assuming that the virus of varicella can be fixed either in the skin, or in the spinal ganglia, or in a segment of the cord, producing, respectively, an attack of chicken-pox, a herpes zoster, or the "zoster fever" of Landouzy. He feels that the dualist view is based rather on sentiment and theory than on precise, carefully observed facts amd serological proof. In this soldier each chicken-pox eruption was accompanied by an identical herpetic eruption, suggesting very strongly that the two eruptions depended strictly on a common ætiological factor. Dr. R. L. Thorold Grant[2] describes a case of varicella breaking out in a woman of 37 with severe bilateral herpes, and Dr. D. E. H. Cleveland[3] one of herpes in a mother, followed after the correct incubation period by varicella in her daughter, and then, after a second incubation period, the appearance of a typical varicella rash, accompanied by erythema nodosum of the legs, on the mother. Both these cases seem to support the theory of common origin. Again, Dr. von B. M. van Driel[4] had a Javanese man of 28 with a typical varicella rash following a herpes of the left upper arm, and another of 26 with a herpes following a varicella. He made the experiment of inoculating four children of varying ages, and two young men with fluid from herpetic blebs. Except for one of the young men, none of the subjects showed more than a slight erythema at the site of injection; this man fell ill 12 days afterwards with typical varicella. The children might have been expected to remain immune; some would think herpes a more likely reaction than varicella in the young man, but presumably chicken-pox is not endemic in Java.

The arguments in favour of common origin were well summarised by Dr. Flandin in the discussion on the first case. He said that, histologically, the vesicles in the two conditions are identical; biologically, there is an absolute specificity of the fixation reaction between the two; and, experimentally, the inoculation of the contents of herpes vesicles into children who have not had chicken-pox gives the same results as "varicellisation." Inoculation with herpes confers immunity to chicken-pox. Epidemiologically the incubation periods correspond. Dr. M. A. Netter and Dr. Achille Urbain have recently investigated the deviation of the complement in these cases. Out of 100 herpes subjects, of whom 84 had had no apparent contact with varicella, 93 showed deviation of the complement, whether the antigen were taken from varicellar or herpetic vesicles. Similarly the results with varicellar serum were identical with either antigen. These workers concluded that poisons like arsenic, bismuth, and mercury produce herpes by acting as "agents provocateurs" of a virus which up till then had been harboured with impunity by the patient.

At the Brussels Congress in 1926, Flandin suggested that chicken-pox might be an early manifestation—and, indeed, herpes is rare in children—while herpes was the later systematised form, appearing in a subject immunised against chicken-pox. On this hypothesis an attack of herpes would be a reinfection or the result of a lowered immunity from some infectious or toxic cause.

THE TREATMENT OF ACUTE AND CHRONIC LARYNGITIS.

To the Editor of THE LANCET.

SIR,—Mr. Mollison, in his article on this subject in your issue of July 21st, mentions that faulty methods of voice production should be corrected. May I say that this should always include instruction in breathing through the nose, in view of the fact that one of the causes of laryngitis is inhalation of dust.

Most people are under the impression that they always breathe through the nose because they do not sit with their mouths open when not talking or singing. They do not realise that they breathe through the mouth when vocalising, and this means that the air is taken unwarmed, unmoistened, and unfiltered direct into the pharynx, larynx, windpipe, and lungs. Few know that it is possible to breathe through the nose without closing the mouth; indeed, many voice teachers state that it is impossible. At most it is conceded that though it *can* be done it involves undue pause and the making of a loud sniff. But both these objections are obviated if the necessary practice be carried out to make the dilators of the nostrils, and the soft palate, active and flexible. Breath can then be taken quickly and quite silently through the nose with the mouth open.

All voice users should be taught this, and to none is it more important than to actors and auctioneers, who speak in places that are laden with dust. If they will obtain instruction in the use of the voice, learn to breathe always through the nose, and follow the direction of their medical man to sniff up their nostrils a little of the medicated emollient that has been prescribed for them (and which, on inquiry I usually find they forget to do), they will be saved considerable pharyngeal irritation as well as the more serious laryngitis.—I am, Sir, yours faithfully,

KATE EMIL BEHNKE.

The Moor House, Lane End, Bucks, July 26th, 1928.

THE COST OF MOTOR ACCIDENTS.

Sir Arthur Stanley last week opened the new out-patient department of the Wolverhampton and Staffordshire Hospital, which has been erected as part of a reconstruction scheme to cost £45,000. He said that figures which had been compiled for him showed that the extra cost of motor accidents to the hospitals is £250,000 a year, of which some £30,000 is recovered from insurance companies. In addition to a large reception hall, the new department includes consulting and examination rooms for ear, throat, and nose cases; two consulting rooms for physicians and two for surgeons, with four examination rooms; rooms for the treatment of fractures and orthopædic cases; a small operating theatre; sterilising and anæsthetic rooms; a recovery room with eight beds for use after minor operations; an isolation room and a venereal diseases department.

Corrigendum.—In our report last week (p. 189) of the International Conference on Cancer, subject, "Diagnostic Methods," the remarks attributed to the Chairman in closing the discussion were actually made by Sir William Willcox.

Medical Diary.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

TUESDAY, August 7th.—10 A.M., Medical Registrar: Medical Wards. 2 P.M., Mr. Addison: Operations. 2 P.M., Dr. Shaw: Medical Out-patients.

WEDNESDAY.—10 A.M., Dr. Owen: Medical Diseases of Children. 2 P.M., Dr. Scott Pinchin: Medical Out-patients. 2.30 P.M., Mr. Donald Armour: Ward Visit.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Mr. Donald Armour: Operations. 2 P.M., Mr. MacDonald: Genito-Urinary Department.

FRIDAY.—10 A.M., Dr. Pritchard: Medical Wards. 12 noon, Dr. Ironside: Clinical Demonstrations. 2 P.M., Mr. Sinclair: Surgical Out-patients.

SATURDAY.—9 A.M., Mr. Vlasto: Throat, Nose and Ear Operations. 10 A.M., Dr. Owen: Medical Diseases of Children.

St. Cyres Lecture

ON

HEART AND CIRCULATION IN A TROPICAL AVITAMINOSIS (BERI-BERI).

Delivered at the National Hospital for Diseases of the Heart, London,

BY PROF. K. F. WENCKEBACH, M.D., F.R.C.P.

(*From the First Medical Clinic, Vienna.*)

FORTY years ago, as a young doctor in my own country, I was intimately acquainted with the two Dutch scientists, Pekelharing and Winkler, who, as a government committee, had studied beri-beri in the Dutch Indies. In those days nothing was known of its ætiology; my authorities believed it to be an infectious disease. Eykman and Grijns had not yet discovered its causation, but many of its clinical features had been described, and it was generally known that, to quote a British poet—

> "Beri-beri is very, very
> Hard on the nerves——,"

and, moreover, very "hard on the heart" also. I was greatly impressed by the astonishing facts that patients seem to die of complete failure of the right heart only; that the opinion (accepted as a dogma) was that this heart failure must be due to a degeneration of the vagus nerve; that patients may die 24 hours after having been in seemingly good health; that there was an "idiopathic" hypertrophy of the whole heart with evident lack of contractile strength as the chief characteristic; and that vitamin B had a miraculous effect on a heart which refused to react to any cardiac drugs—all these facts suggested to me the existence of some quite peculiar morbid process. Some seven years ago I explained this important problem to a young friend, Dr. Aalsmeer, a lecturer on internal medicine at the medical school for native doctors at Surabaya (Java). He devoted a good deal of time and interest to the question and last autumn returned from the Dutch Indies with complete clinical records of the cardiac aspect of the disease. These data, illustrated by X ray photographs and electrocardiograms, provide us with a veritable "natural history" of the circulatory apparatus in beri-beri cases.

CAUSE, SYMPTOMS, AND TREATMENT OF BERI-BERI IN GENERAL.

The generally acknowledged ætiology lies in the absence of an accessory food factor (vitamin B), contained in the bran of rice and cereals. The disease makes its appearance where polished rice is the exclusive diet. Proof of this pathogenesis is furnished by the results of the sole treatment—viz., addition to the diet of vitamin-containing foodstuff, such as rice-bran, bran extracts, or a certain bean, known in Japan for over ten centuries (*Phaseolus radiatus*. Malayan: katjang idjoe). Even in very severe cases it relieves the serious symptoms. The principal pathological changes are:—

(*a*) Degenerative processes in the peripheral nervous system, damaging and even destroying the peripheral motor and sensory, as well as the sympathetic and parasympathetic elements. The symptoms are those of extensive polyneuritis.

(*b*) Anasarca and serous effusion in the large cavities. In chronic cases there may be a condition of extreme general atrophy and dryness of skin and tissues, the so-called "dry form."

(*c*) Heart disease, characterised by general feebleness of the circulation, palpitations on the slightest exertion, swelling of the liver and œdema, with general swelling of the limbs. This heart failure is very often the cause of death.

CLINICAL ASPECTS OF HEART AND CIRCULATION.

I rely on the work of Aalsmeer, correlating it with the earlier work of Vedder, Castellani, Chambers, and Manson, in English; of Scheube, Nocht, and Mense in German; of the Dutch authors Pekelharing and Winkler, Kieviet de Jonge, de Langen; and the many Japanese contributions, culminating in the important work of Shimazono, whose conceptions are in many respects identical with those of my collaborator.

The following points may now be taken as well established:—

1. From the beginning of the disease the whole heart, right and left, is enlarged; X rays show not only an enlargement to the right, but also bulging of the left auricle in the so-called "taille" (left upper border) of the heart shadow. The left ventricle, too, is clearly larger than normal. It is impossible to decide whether, in this first period, the enlargement is due to dilatation alone or to hypertrophy of the muscle wall also.

2. This enlargement and corresponding failure of the heart increases more or less rapidly, sometimes in a few hours, *but chiefly involves the right heart.* The prevalence of right heart failure and right heart widening and hypertrophy is mentioned by everyone who has studied the disease at the bedside and post mortem. A remarkable clinical manifestation is the disappearance of the apex-beat and the substitution for it of a curious wriggling, fluttering motion of the heart muscle, which the patient himself feels and which is easily seen on inspection and felt by palpating with the whole palm of the hand.

3. Increasing stasis takes place in the liver and venæ cavæ, and in acute cases this causes an enormous, painful swelling and bulging of the liver, ascites, and sometimes sudden death.

4. Even in the most serious cases there is never any irregularity of the heart, no extrasystoles, flutter, or fibrillation. The electrocardiogram never shows any disturbance of stimulus conduction. The ventricular complex is perfectly normal, and the size of the different waves rather exaggerated, the only peculiarity being a certain degree of preponderance of the right ventricle.

5. The pulmonary circulation is completely free from any sign of stasis, œdema of the lungs only showing itself in the last moments before death. There is no other disease of the lungs, no true emphysema, no arterio-sclerosis or spasm of the pulmonary arteries, which might cause right heart failure.

6. Apart from variations in the course, dependent on the relative intensity of neuritic manifestations on the one hand and of cardiac disease on the other, two forms of beri-beri are generally recognised—namely, a chronic and an acute, so-called pernicious and usually fatal form. The latter is now much less often seen than it used to be, since specific treatment has almost abolished it.

7. The whole series of heart remedies and diuretics (digitalis, strophanthin, caffeine, theobromine, thyroid, novasurol, salyrgan, &c.) is of no real use for the beri-beri heart. Vitamin B alone is an immediate and usually complete success. At autopsy the heart shows enlargement of its cavities and apparent hypertrophy of its walls, both much more pronounced in the right side of the heart. Microscopically there are no striking changes in the heart muscle-fibres and no inflammation.

DILATATION AND FAILURE OF THE RIGHT HEART.

The first unsolved problem of the beri-beri heart is the extreme widening and failure of the right heart in contrast with the relative smallness of the left ventricle and the absence of pulmonary stasis. This seems the more enigmatic, as there is proof that both sides of the heart suffer at the beginning of the disease. The soft and frequent pulse, however, the curious wriggling motion of the enlarging heart, and the progressive over-filling of the proximal parts of the venous system (v. cavæ and liver), are undeniable signs of the heart's incapacity to convey the whole quantity of affluent blood from the venous into the arterial side of the vascular system. Clinical experience has taught me *that in such cases of increasing insufficiency of the whole heart the right heart is doomed beforehand to suffer much more than the left, and even to suffer to the profit of the latter.* If the strength of systole is decreasing in both ventricles equally, the moment will come at which both ventricles will fail to discharge their contents completely. A larger amount of residual blood than normal is retained in the heart. This larger post-systolic ventricular blood volume, together with a normal onflow of blood during the diastole, must necessarily result in a greater filling of the heart at the beginning of the next systole. This increased load will soon become too much for a heart already unable to discharge a normal quantity of blood. The output will become smaller and smaller, the filling of the arteries will be less, and the diastolic filling of the heart and the venous stasis before the entrance port of the heart must both increase. This being so, two factors will establish a marked difference between the right and left heart.

The first of these is the anatomical inequality of the two ventricles, the right being of lighter build, and provided with a thinner wall. The tricuspid valves are implanted on a much weaker ground than the mitral; there is no strong fibrous ring supporting them, they are condemned to share the distension of the right ventricle, and consequently are more liable to incompetence. Once this incompetence is established, blood passes from the right heart backwards into the veins and liver and the arterial output of the right ventricle is greatly reduced.

A still more important factor is at work. In the blood stream, moving "quasi in circulo," the right heart is located higher up the river than the left. As a consequence, the right heart has to deal under all circumstances with the whole volume of blood returning from the periphery to the heart, *the left heart not receiving more blood than the right heart is able to transmit.* Consequently the right heart is all the time struggling for life against an ever-increasing overfilling and widening, but the left heart is spared a similar burden. *The more the right heart suffers and fails, the safer the left heart becomes,* working under easy conditions and decreasingly threatened by such factors as might lead to overfilling and dilatation.

In such circulatory disturbances, despite a smaller output of the left heart, this smaller minute volume will reach the great veins and the right heart in due time. This holds good even in severe degrees of mitral stenosis, in which an extremely high arterial blood pressure may be maintained. Even after the final standstill of the heart in the first moments of death this function of the arterial wall (perhaps the last of life) is maintained, so that post mortem the arteries are found empty and the venous system filled. Therefore a smaller supply of blood to the aortic system cannot be expected to relieve the difficulties of the right heart in the same way as a smaller supply to the pulmonary arteries relieves the left heart.

These explanations make it possible to understand the cardiac and circulatory phenomena of beri-beri, the initial widening of the whole heart, the ever-increasing bulk of the right heart, the ever-decreasing cardiac systolic output, and the progressive engorgement of the proximal venous system, venæ cavæ, and liver. It is now easy to see how in acute attacks of beri-beri a sudden failure of the right ventricle with tricuspid incompetence puts the great veins and the liver under systolic ventricular pressure. These are distended to the highest degree and sudden death ends a condition of extreme suffering, the horror of which was so dramatically described by Manson in his handbook of tropical diseases. Throughout this unsuccessful struggle of the right heart the lung fields on the X ray plate are quite clear; there is no lung stasis, no râles, and no pulmonary œdema, and the left heart is not greatly enlarged but, on the contrary, is smaller and poorly filled. A small and rapid, but fairly palpable, pulse gives proof of the relative competence of the left ventricle, until at the last moment before death the latter loses its systolic power, succumbs, and leaves the lungs with stagnating blood and signs of ante-mortem œdema.

This simple mechanism, which explains the whole circulatory complex of beri-beri and the post-mortem findings, has great importance for general cardiology. The so-called safety-valve action of the tricuspid valve, hepatic stasis relieving the lung from threatening high tide, is familiar to a good number of us, but well-defined conditions of functional heart disease, involving both sides of the heart equally, are rather rare. They may be found in the course of acute infectious diseases (pneumonia, diphtheria, and others), but here so many different toxic and reflex influences complicate the picture that the separate influence of each is not easily discriminated. Another condition in which both sides of the heart are hampered in their action to exactly the same extent is rapid paroxysmal tachycardia and auricular flutter and fibrillation. In otherwise normal hearts it has been possible to show *that here also there is marked stasis in the large veins and liver coincident with absence of lung stasis, râles, and dyspnœa.* Since James Mackenzie discovered the change of circulation caused by the onset of what he called auricular paralysis, now known as fibrillation, in long-standing mitral stenosis, we have been acquainted with sudden, painful swelling of the liver; from personal experience this change is often accompanied by a striking improvement in respiration, and relief of the suffocating dyspnœa.

Once I recognised this mechanism, I was able to find it in a great many cases of slowly progressive, general myocardial weakness. Careful treatment, with well-apportioned doses of digitalis and diuretics, may cause lung œdema and swelling of the liver to disappear, even in extreme conditions, but only for a time. These intervals, during which equilibrium between the right and left heart is maintained with difficulty, become shorter and shorter, until at last treatment fails and the patient dies in a few hours. In many of these cases of recurrent heart failure the first and chief symptom is a rapid and very painful swelling of the liver. Even in rapidly fatal cases the same symptoms may be found, râles and lung œdema only showing themselves during the last hours of life.

In all these conditions the curious relationship between right and left heart failure may be recognised, but nowhere is it so uncomplicated, so regular, and so easily demonstrable as in the beri-beri heart. Thus there is a law of circulatory correlation between the two sides of the heart which may be formulated as follows: *In equal and increasing feebleness of the whole heart muscle the patient suffers most and dies from the failure of the right side of the heart only.*

Shimazono and Aalsmeer do not accept the conventional view that degeneration of the vagus fibres is the cause of the heart failure. Considerable dilatation of the heart may be present long before the first manifestations of polyneuritis. There is no parallelism between the degree of degeneration of nerve-fibres and that of the heart affection; indeed, it is the strong, apparently still healthy patient who seems to be most liable to the serious sudden acute attacks, in contrast with the patient whose first symptoms are those of palsy from polyneuritis. Aalsmeer is probably right in thinking that the relatively good nerve-fibres of the strong man enable him to undertake an amount of exercise which asks too much of his already weakened heart and induces the sudden attack of heart failure.

This vagal factor being unacceptable, we have to seek other clinical facts that would reveal the one potent unknown factor of this disease. *The* first hint is given by reasoning that, in our explanation of the development of myocardial failure in beri-beri, there seems to be no place for the hypertrophy of the heart muscle so often described. Why *should* the muscle that from the very beginning is showing all the signs of reduced contractile force and lessened output become hypertrophic? Such conceptions as "hypertrophie passive par faiblesse du myocarde," or "the individual fibres becoming weaker . . . an attempt is therefore made to compensate by increasing the number of fibres—i.e., hypertrophy," do not elucidate the problem. The only way out of the difficulty seemed to be to look for another explanation of the post-mortem findings of increased weight of the whole heart and increased thickness of the muscle walls.

Aalsmeer found that, even in the worst conditions of failure, the beri-beri heart gives a perfectly normal electrocardiogram, without arrhythmia, extrasystoles, heterotopic rhythms or disturbance of conductivity in the bundle or in the conducting fibres of the ventricle. This fact reminded me that the old observations of MacWilliam record non-contracting heart muscle without disturbance of conductivity. Thirty years ago Engelmann found that the frog's heart muscle when immersed for a short time in water loses its contractility but retains its excitability and its power of stimulus conduction, showing that this phenomenon, discovered by Biedermann in voluntary muscle, holds good also for heart muscle. Later de Boer demonstrated that the swelling of the heart muscle, caused by the water, reduces mechanically the contractile power of the muscle-fibre, but at the same time the electrocardiogram may continue completely unchanged. Skramlik, Lusanna, Zondek, and Kraus demonstrated the same phenomenon for other forms of water retention in muscle-fibres, and even found that the size of the waves of the electrocardiogram may be enlarged and the rate of conduction increased. The presence in beri-beri also of this strange contrast between evident weakening of the heart muscle and the undisturbed or accelerated automatic excitatory processes suggests that here also *the nature of the affection might be water retention* ("Quellung") *with consequent swelling of the heart muscle-fibres*, and that this swelling, rather than a true hypertrophy, may be the cause of the increased weight and thickness of the heart muscle wall as found post mortem.

THE WATER RETENTION HYPOTHESIS.

Many arguments support this hypothesis. A few months ago Tiemann showed that striated, in contrast with smooth muscle-fibres, swell in water and in all hypertonic solutions. The gain in weight and the swelling, due to the quantity of water taken up, is less in heart muscle than in common voluntary muscle. If the same process is at work in beri-beri we should expect to find the skeletal muscles swollen at the same time as the heart. This swelling is, in fact, typical of the disease, especially at the beginning, long before general tissue œdema or signs of nerve degeneration appear. Swelling is most conspicuous in the muscles of the calf, which are very painful in walking and on being pinched. Pekelharing, Winkler, and Nocht compared the condition with the "pseudo-hypertrophic stage" in progressive muscular atrophy of childhood.

On this hypothesis we should expect that no treatment can succeed which does not free the heart muscle from its surplus water and drain the muscle-fibre. When vitamin B is given, the heart rapidly diminishes in size and recovers its power of contraction, and the skeletal muscles share in this process. The hard, thickened, and painful muscles of the calf melt away, as snow in the sun, to muscles of normal size and function. De Langen, in his new monograph on beri-beri, mentions this rapid disappearance of the swelling and equally rapid cure of the motor paralysis, less than 24 hours after taking vitamin B-containing food. This remarkable improvement is accompanied by a marked increase in the secretion of urine. Scheube states that katjang idjoe had the reputation in Japan a thousand years ago of being a good diuretic. Of recent years the diuretic action of rice-bran and katjang idjoe has been specially investigated by Japanese scientists.[1] From the extensive work on the regulation of water exchange by Magnus and by the Vienna Pharmacological Institute (E. P. Pick, Molitor Baer) we learn that striated muscle may take up and, under certain circumstances, can retain large quantities of water injected into the blood or taken by the mouth. Our muscular system may be regarded as one of the biggest water reservoirs, and its contents do not appear on the balance of intake and output.

Recent research work by Tsunoda and Kura[2] gives important information concerning the anatomy and treatment of beri-beri. In pigeons exclusively fed on polished rice the sensory nerves and their endings in the skin show curious primary regressive metamorphosis accompanied by swelling and other changes in their microscopical appearance. After the injection of small doses of vitamin B all these changes and their clinical consequences disappear rapidly. The endings of the sensory and motor nerves improve rapidly within five hours after the injection. Twenty-four hours later the histological appearance is practically normal.

The conception of water-retention in the heart muscle-fibre explains all the symptoms and peculiarities of the beri-beri heart, which thus constitutes a hitherto unrecognised and unique form of heart muscle disease. Before trying to bring this curious pathogenesis into relation with other well-known facts of physiology and general pathology, I must mention an equally unique phenomenon in the symptomatology. Not only is the electrocardiogram normal during the whole course of the disease, but the rate of conduction is increased and the atrio-ventricular interval is shortened. Moreover, conduction quickens as the heart failure progresses. In the most serious and acute cases the shortest atrio-ventricular intervals were found when the patient seemed to be in imminent danger of death. With recovery the conduction slowed down to normal, even with slowing of the rate of the heart beat. The fact that the same phenomenon was found experimentally in water-swelling of the heart muscle is a strong argument in favour of the identity of this condition with beri-beri heart.

THEORETICAL CONSIDERATIONS.

It seems very probable that water-retention may be the primary cause of other manifestations of beri-beri and, in the first place, of the important degenerative processes in the whole peripheral nervous system. We have already seen that the swelling of nerve-endings in chicken beri-beri disappears completely a few hours after vitamin treatment. The microscopical anatomy of nerve-fibres and ganglion cells in beri-beri accords well with this conception, and it should not be forgotten that although motor and sensory paralysis may be found, as in polyneuritis, the primary affection of the nerve element in beri-beri is not inflammation. It is the general opinion that the anasarca is not so much secondary to heart failure, as essentially an imbibition process of the tissues. Other organs may show temporary swelling at the same time. Some of the glands seem to possess a special predisposition for this kind of water-retention in beri-beri, just as striated muscle is the first tissue to swell while smooth muscle escapes. A familiar pathological finding in this disease is swelling of the mucous lining of the gall-bladder. Kieviet de Jonge mentions a curious broadness of the face, recalling parotitis, and he found that there is enlargement of both parotid glands, the nature of which, he says, is "not œdema." Stepp thinks it probable that some of the glands, especially those secreting saliva, ceased to function.

It would be astonishing if beri-beri were the only disease in which water-retention directly damaged the heart. When an ailing heart does not react to heart drugs we generally suspect a desperate anatomical and functional condition of the myocardium; it seems possible that the cause found in beri-beri plays a part in the development of such events and might be removed by analogous forms of treatment. The first disease to remember in this connexion is myxœdema, where there is water-retention as a consequence of insufficient thyroid secretion (" Quellung "), and where water is expelled (" Entquellung ") by thyroid treatment. A case of atypical myxœdema may be shortly related here:—

---

[1] Japan Jour. of the Med. Sciences, 1927, viii.

[2] Virchow's Archiv, 1928, p. 267.

Some 20 years ago a small Frisian community sent a poor man to the medical clinic in Groningen because he was more or less stupid and so easily tired that he was incapable of any bodily work. His face showed a certain degree of imbecility or apathy, and his muscular function was greatly diminished; but his build was Herculean. There was no trace of œdema, the face was not swollen, and the heart seemed normal. The muscles were not only big, but very hard and of abnormal consistence; I thought this might be myxœdema of uncommon localisation. A few thyroid tablets had a most astonishing effect; the firm voluminous muscles that were very painful on pinching became thinner, softer, and fit for use again. On palpation the peculiar sensation of rolling muscle bundles returned, leaving only a few hard nodes, which disappeared in a day or two. In a week's time the normal intellect of the man had returned and he was sent back to his village and advised to take small doses of thyroid indefinitely. To the great satisfaction of his community he proved completely cured and able to do regular work, but with less Herculean muscles.

The absence of heart and nerve lesions, on the one hand, and the inactivity of thyroid in beri-beri on the other, prove that this case was not beri-beri, and the two conditions of different nature.

Another important difference was noted by Aalsmeer. In both diseases there is a greatly increased skin-resistance in the patient to the electrocardiogram; more in beri-beri than in myxœdema. But the deflections of the string are very small in myxœdema and at the least normal, or sometimes much larger than normal, in beri-beri.

These clinical facts point to the quite peculiar and specific nature of the swelling of the striated and heart muscle, which is certainly not a condition of œdema.

HEART HORMONES AND AUTOMATINS.

Our subject forms a bridge between scientific research at the bedside and modern experimental work on heart " hormones " (Haberlandt) and " automatins " (Zwaardemaker). Rigler[3] found that vitamin B, isolated as a pure chemical substance by Jansen and Donath, belongs to this group of substances. He believed it to be identical with histamin. The fact that the organism itself produces substances which are able to bring an experimentally stopped heart and its automatic functions back to life has already induced experimental workers to recommend these substances for the treatment of heart patients. The beri-beri heart shows that at least in some rare conditions the revival of a seemingly lost heart is possible. There are doubtless a great number of different conditions causing standstill of the heart, and doubtless we shall hear, in the course of time, of a great number of different substances which may help. The beri-beri heart shows that not every heart that stops its systolic action has lost its regular automatic vital function. The automatism may go on undisturbed, but is prevented from manifesting itself by lack of conductivity or, as in beri-beri, by interference with contractility. In such cases the active substance which restores the regular function should not be called an automatin; what happens in the heart is not revival from death, but release from bondage.

SUMMARY.

My subject shows eloquently that careful study of the sick and their symptoms, and free experimental research are equally indispensable to the advancement of medicine.

It teaches us the existence of a law of circulatory correlation between the left and the right heart, working along simple mechanical lines of considerable clinical importance.

It leads us towards the better understanding of a disease, of which the successful treatment had already been found by experience at the bedside.

It brings us into close contact with the most modern biological problems of water exchange, of hormones, of sudden death, and revival of vital functions.

It seems permissible to formulate the hypothesis that the fundamental process in beri-beri is water retention and the consequent swelling of certain vital tissues, especially nerve and striated muscle.

THE LATER RESULTS OF PARTIAL GASTRECTOMY.*

By NORMAN C. LAKE, M.D., M.S., D.Sc. Lond.,
F.R.C.S. Eng.,

SURGEON TO CHARING CROSS AND BOLINGBROKE HOSPITALS; ASSOCIATE EXAMINER IN SURGERY, UNIVERSITY OF LONDON.

FEW subjects have received more attention or have been the cause of intenser controversy during recent years than that of the nature and treatment of gastric and duodenal ulceration. From the surgical point of view the discussions have, for the most part, ranged around the relative merits of partial gastrectomy and gastro-enterostomy. It is not proposed in this article to consider partial gastrectomy as a treatment for new growths—for here the obligations of the surgeon are sufficiently clear—but to limit the review to cases of apparently non-malignant ulceration.

It will be well at the outset to summarise the standpoints taken by the several schools of thought at the present day. (1) The first school believe that operative treatment should never be adopted in the absence of acute complications such as perforation; they maintain that the symptoms can be adequately controlled by purely medical measures. For obvious reasons this group consists almost exclusively of physicians. (2) The second group comprises those who think that operation may be occasionally justified in very persistent cases, and especially in the presence of such complications as pyloric stenosis. Into this group fall many physicians and a few surgeons who have been unfavourably impressed by the recurrence of symptoms or the onset of jejunal ulceration after gastro-enterostomy. (3) The majority of English surgeons belong to the third group and favour gastro-enterostomy for chronic cases, after medical treatment has been given a trial, but would treat all acute cases medically. (4) Others advocate gastro-enterostomy, with or without pyloric exclusion, for practically all cases. (5) Yet another school consider that for the majority of cases of gastric ulceration partial gastrectomy is indicated, but perform gastro-enterostomy for duodenal disease. (6) The last school believe partial gastrectomy to be the operation of choice in all cases, and would always perform it for both gastric and duodenal ulceration if the technical difficulties are not insuperable.

With such diversity of opinion the only safe guide is a critical and, as far as possible, unbiased examination of the results. Since this article will deal only with the surgical aspect it is essential, as a prologue, to give reasons why the claims of the first school, that surgical treatment is unnecessary, cannot be entertained. Unfortunately, perhaps, for the surgeon's proper judgment, the great majority of the cases upon which he operates have already received a prolonged course of medical treatment, a circumstance likely to prejudice his opinion of these claims. The discovery of signs of old healed ulcers is offset by the presence of the fresh outbreak for which the operation is undertaken. The treatment therefore, even in such cases, has done little more than allow the original ulcer to heal without removing the cause. Post-mortem evidence of completely healed ulcers is, in my experience, much rarer than that found at operation for a fresh outbreak; it thus appears reasonable to conclude that medical treatment can rarely bring about permanent cure. Moreover, relief of symptoms is not necessarily accompanied by cure of the ulcer.

---

* Being a paper delivered before the South-West London Post-Graduate Association.

The list of possible surgical procedures is a long one, and each operation has its advocates and indications. 1. Posterior gastro-enterostomy. 2. Anterior gastro-enterostomy. 3. Gastro-enterostomy with pyloric exclusion or entero-anastomosis. 4. Finney's operation. 5. Local excision by knife or cautery. 6. Local excision and gastro-enterostomy. 7. Sleeve resection. 8. Partial gastrectomy (Billroth 1 and 2; Polya and its modifications). 9. Jejunostomy. 10. Denervation. Of these only gastro-enterostomy and partial gastrectomy will be compared, the indications for the others falling outside the scope of this article.

Data.

The cases reviewed occurred in the author's practice during the five years 1922–27, and none of less than one year's post-operative history are included. The total number of gastric operations was 221, and of these 65 were partial gastrectomies and 71 gastro-enterostomies; the percentage of gastrectomies, however, rose from 5 per cent. in the first year to 62 per cent. in the final year under review. In the first instance inquiry was made by a circular letter including a series of simple questions designed to overcome any reluctance on the part of the patient to record unsatisfactory results; for previous experience had shown that patients hesitate to state slight inconveniences.

As many patients as possible were then personally interviewed and re-examined; plenty of volunteers were found for additional investigation by bismuth meal, test meal, blood counts, bacteriological tests, &c. In this way the subsequent history of a considerable number has been obtained in detail, with records of the ultimate results of the special tests. In classifying the results, those who, in addition to giving entirely satisfactory answers to the questions, added enthusiastic comments about their health, were called "satisfactory + +." Those who answered all questions in a gratifying manner without comment were classed as "satisfactory +." Where the patient had received complete relief of symptoms but complained slightly of occasional fullness and constipation the result was called "satisfactory." Patients who stated they were better but still had attacks were "unsatisfactory," while patients with recrudescence of symptoms or development of fresh ones were "unsatisfactory +." One of the questions related to the type of food taken, and unless the reply was that all foods were taken without restriction the patient was not placed in the "satisfactory" group. Of the 65 gastrectomies 8 were subsequently proved by section to be carcinomatous ulcers, and have therefore been placed in a separate table.

Sat.	12			

Thus 95 per cent. of the partial gastrectomies have no symptoms of any sort and are able to take all kinds of food without restriction, and 51 per cent. of the gastro-enterostomies come into the same category. Only 2·5 per cent. of the gastrectomies are unsatisfactory, but 36 per cent. of the gastro-enterostomies fall under this heading. There can be no doubt, therefore, that from the point of view of complete and permanent relief of symptoms gastrectomy is a much more satisfactory operation than gastro-enterostomy, although 63 per cent. of patients treated by the latter method are cured or improved.

The mortality figures rather counterbalance this satisfactory conclusion, for 6 of the gastrectomy cases died within four weeks of the operation, 2 of hæmorrhage, 2 of pneumonia, and 2 as the result of gastric fistula following the Billroth 1 type of anastomosis. Both these last two were debilitated patients with enormous ulcers (one malignant) very adherent to surrounding structures, and no other procedure seemed possible. The Billroth 1 operation is notoriously liable to leakage if there is the slightest tension on the anastomosis, which is difficult to avoid after an extensive resection. It is legitimate, therefore, to exclude these from the ordinary mortality. They come early in the series, and with additional experience it is certain that they would now either be left alone or treated by jejunostomy. The other four cases constitute a mortality of 6·3 per cent., a figure capable of reduction, probably to half, with care. On the other hand, there was no mortality in the gastro-enterostomy series. Further analysis of the mortality figures gives the following:—

	Per cent.		Per cent.
Gastro-enterostomy	0	Billroth 2	7·5
Sleeve resection	20	Billroth 1	100
Polya	0		

The 20 per cent. for sleeve resection is obviously misleading, as there were only five cases in the series and the death of one from hæmorrhage was due to the use of catgut subsequently found to be defective. According to these results the Polya would appear to be the safest type of gastrectomy, but the total number of each type performed must be taken into consideration.

Gastro-enterostomy without perforation	61	Polya	18
Sleeve	5	Billroth 2	40
		Billroth 1	2

Even then the Billroth 2 operation is found to have the greater risk, but there was no mortality when it was performed in two stages. The further statistics of the gastrectomy cases are as follows:—

Male, 46	Average age,	39	Incidence of carcinoma cases	13 per cent.
Females, 17	,,	44		12 ,,

The types and position of ulcers were: gastric (body) 12, gastric (pyloric) 5, duodenal 6, doubtful (pyloric) and not mentioned 21, multiple 6, jejunal 7, carcinomatous 8. This list only records the position of the chief ulcer and does not take any account of healed scars or other small ulcers. Had these been included the percentage of multiple ulcers would have been about 90.

After-results of Gastrectomy.

All the gastrectomy cases have gained weight since the operation, some of them as much as 3 st., and they all look remarkably healthy. In one or two cases there appears to have been an excessive deposition of fat, and two mentioned the development of an abnormal desire for highly spiced foods.

Practically all the cases had fractional test-meals carried out shortly after operation, and with one exception showed complete achlorhydria. Those taken after an interval of several years demonstrate quite conclusively that the achlorhydria is permanent. None of them showed the slightest trace of free hydrochloric acid. The average total acid was less than 10, and the average total chlorides in the absence of bile 29; when bile was present this rose to over 70. Typical examples are given in Figs. 1 and 4. Bismuth meals, also conducted after a long interval, show that the remnant of stomach undergoes considerable increase in size; emptying is rapid, never taking longer than an hour and usually much less. The stoma in the Polya and Billroth 2 operations lies more or less horizontally, and is fairly well defined in the radiograms. There is no radiographic evidence of any effect upon the movements of the small or large intestines.

Blood examination revealed a high count corresponding to the patient's appearance of health; no.

case showed less than 4,800,000 red cells. The average of all the counts gives—

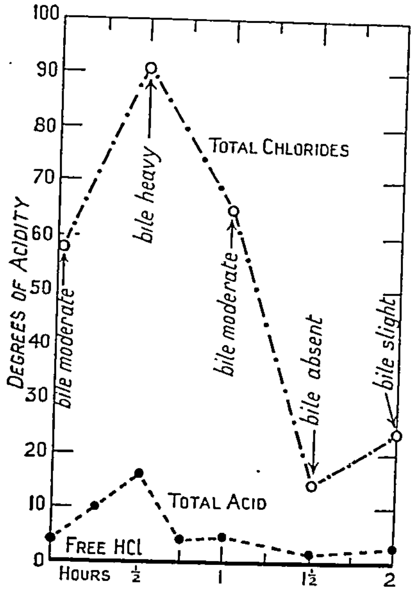
Red blood cells	5,250,000	Eosinophils	1·5 p.c.
Hæmoglobin	91·2 p.c.	Basophils	0·5 "
Colour-index	0·84	Large hyalines	5·4 "
White blood cells	7,160	Lymphocytes	30·4 "
Polymorphs	61·8 p.c.		

Bacteriological examination of the teeth, gums, tonsils, and throat in a series of cases yielded streptococci in several, but in no case were they hæmolytic.

The reasonable deductions from these statistics are that gastrectomy gives much more satisfactory ultimate results than gastro-enterostomy; that it has a mortality of about 7 per cent., whereas there is no mortality from gastro-enterostomy; that jejunal ulceration does not occur after gastrectomy, whereas a proportion of the gastro-enterostomies have symptoms suggestive of such ulceration, and subsequent gastrectomy has sometimes been necessary for definite jejunal ulceration. The exact incidence of jejunal ulceration in the gastro-enterostomies is uncertain because some cases with suggestive symptoms have not been explored, but if we include these the percentage is over 10. The gastrectomies include a large percentage of the more difficult and serious cases with extensive ulcers penetrating surrounding structures, while the gastro-enterostomies include most of the cases of simple duodenal ulceration where the operation was easy.

The total number of jejunal ulcers is too small to allow any definite conclusions, but the accepted idea, that they occur more frequently after duodenal ulceration, is supported, while excision of the original ulcer at the time of operation appears to make no difference to their incidence. Some competent observers deny that jejunal ulceration is rare after gastrectomy, and also state that its incidence is as high after gastro-enterostomy in those cases that show no post-operative acid as in those where acid remains high. There are objections to both these arguments against the importance of hydrochloric acid in the ætiology of jejunal ulceration. It has been definitely established that some patients were not achlorhydric after gastrectomy owing to the very limited resection performed, often little more than a pylorectomy. In the author's experience those cases of gastro-enterostomy which show little or no acid after operation will be found to have had very little acid to start with; this usually means that the ulceration is almost always multiple and of long duration, with the development of a secondary atrophic gastritis (Fig. 2). Under these circumstances the anastomosis may actually be made at the site of mucous ulceration, a condition which would naturally predispose to the development of jejunal ulcer. It will also be obvious that unless the total chlorides are estimated it is impossible to state whether the achlorhydria is due to neutralisation or lack of secretion. In the former case there is no guarantee that the test-meal is an accurate indication of the acid content (or its absence) after ordinary diet.

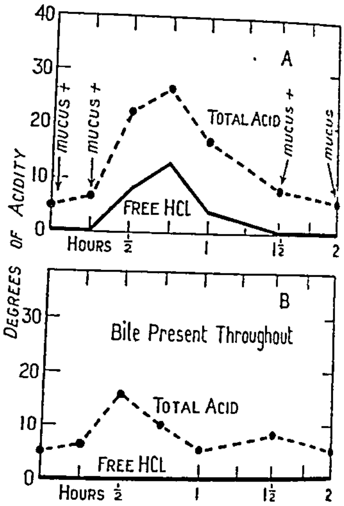
FIG. 1.



Test-meal after partial gastrectomy. The effect of the presence of bile upon the total chlorides is well seen.

If it be agreed that the results of partial gastrectomy are much better than those of gastro-enterostomy, the following questions arise: 1. Is the mortality of partial gastrectomy justifiable? 2. Are the results permanent? 3. Are there any remote effects of the removal of large portions of the stomach? 4. In what way does gastrectomy act?

FIG. 2.



Curves obtained before operation (A), and after operation (B), in a case of prolonged multiple gastric ulceration with atrophic gastritis, showing the small acid content before operation (gastro-enterostomy with cauterisation of the ulcer). The achlorhydria is chiefly due to neutralisation, which would probably not be so complete after an ordinary meal.

The Alleged Deleterious Results of Gastrectomy.

In the series under review the oldest cases have more than six years' post-operative history, while quite a large proportion have more than three years. It may be doubted whether even these periods constitute a true test of permanency, especially since many cases of jejunal ulceration after gastro-enterostomy do not become urgent for many years (certainly more than ten). Nevertheless most patients complain of premonitory symptoms within a limited time (usually a few months) of the operation, whereas the gastrectomy cases all express themselves as entirely free of any warning symptoms. Their general state of health, too, is patently incompatible with continued ulceration. It may be accepted, therefore, as the result of actual experience, that the good results obtained are permanent in the practical application of that term.

It has often been suggested that untoward remote effects may follow partial gastrectomy, especially as all the cases have complete achlorhydria. The relationship of achlorhydria to pernicious and other anæmias has been thought by some to be one of cause and effect; for this reason the blood examinations made some considerable time after the gastrectomy are particularly interesting. No case shows any sign of primary anæmia, but the hæmoglobin and colour-index are rather below normal; the total leucocyte count is normal, the polymorphonuclears being perhaps slightly low. It can therefore be stated with confidence that this series affords no evidence of any deleterious effect of achlorhydria upon the blood count. (Cases of malignant ulceration must obviously be excluded; some of the discrepant results obtained in the past may possibly be explained by failure to separate malignant and simple cases.) No patient is known to have died since the operation, so that any subtle intangible lowering of the resistance to other diseases, especially infections, can be excluded. The stools were not examined bacteriologically, but there were no clinical signs of any abnormal infectivity of the intestinal contents, nor was there any radiographic evidence of nervous or chemical interference with the action of the small or large intestine.

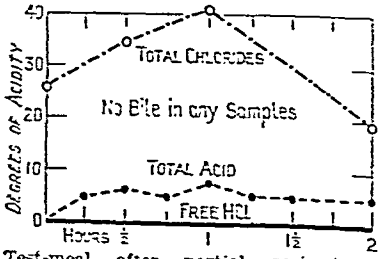
The tendency to excessive deposition of fat in two cases could conceivably be due to some alteration in the metabolism of food, but is probably more correctly explained as an inability of the tissues, often long starved, to deal efficiently with the sudden excess of food products with which the patient, now relieved of his pains, supplies them. In other cases it may be merely the resumption of the patient's normal build and habit. The slight qualitative change in appetite reported by two patients may be due to the removal of a large sensory area from the stomach mucosa, but was too vague and trivial to warrant much attention.

On the whole, then, it seems that there is not an iota of evidence that any remote deleterious effects follow gastrectomy. Indeed, the patients appear to be in a much better general state of health than they had been for many years.

The Mortality of Gastrectomy.

The definite, if small, mortality associated with gastrectomy cannot be dismissed so easily. In this series the gastrectomies include all the most difficult cases, while the mortality associated with any subsequent operation for jejunal ulceration (notoriously difficult to treat and usually demanding partial gastrectomy under the worst circumstances) should be remembered in estimating that of gastro-enterostomy. With these modifications the difference in the mortalities is much reduced, some say equalised. All discussions of mortality are, however, futile until the type of case for which the operation is to be limited is defined. Those who recommend gastrectomy for all cases of duodenal and gastric ulceration agree that the mortality is little greater than that of gastro-enterostomy with its later complications; those who limit the operation to large gastric ulcers state correctly that such conditions are very serious at the start and that, provided the mortality is small, the operation is amply justified. The mortality is capable of further reduction; probably the surgeon's experience is the most important factor, but greater pre- and post-operative care are possible. Transfusion, special dieting, attention to oral sepsis, and especially the postponement of operation upon any signs of infection of throat or lungs should never be neglected. In all serious cases the operation should be a Billroth 2, performed in two stages with a suitable interval.

FIG. 3.

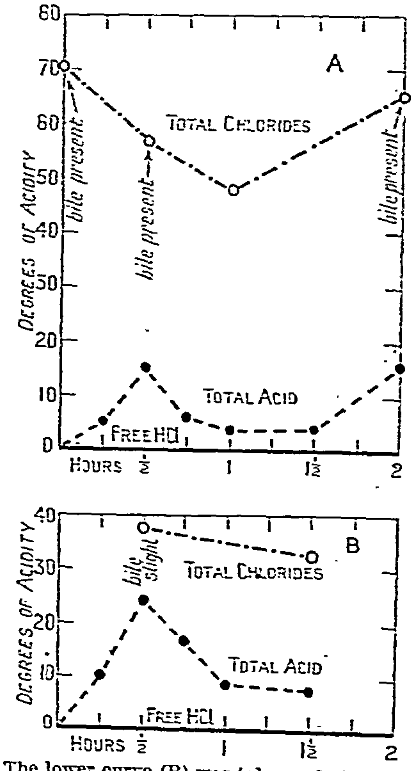


Test-meal after partial gastrectomy, showing achlorhydria and low total chlorides in the absence of bile, indicating that achlorhydria is not merely a question of neutralisation.

After the operation every precaution must be taken to prevent chest complications. The value of extensive splanchnic and field block anæsthesia is doubtful; it was used in a large percentage of these cases without any effect upon the incidence of chest complications, though it probably rendered the convalescence smoother. In most cases the general anæsthetic was intratracheal ether or chloroform, and there was no noticeable difference in the effects upon the lungs. There is no doubt that post-operative "pneumonia" in these cases is due much more to the lowering of vitality and interference with upper abdominal movement than to the type of anæsthetic, so that speed, facility of access, and clean, gentle manipulation are of great importance. The other causes of mortality are definitely avoidable by attention to technique, and there is no reason why it should rise above 2 or 3 per cent. If such a figure be approached there can be no doubt that the operation is not only justifiable but actually advisable instead of gastro-enterostomy.

Among other arguments in favour of gastrectomy is the avoidance of the risk of subsequent malignant change in the ulcer. Some cases not included in this series definitely prove that such a change can occur, even after gastro-enterostomy, but it is certainly uncommon, and the high percentages given by some observers are undoubtedly founded upon a misinterpretation of the premises necessary to establish a diagnosis of malignancy. If malignant change were common, any series of gastro-enterostomies should show a fairly large subsequent mortality from this cause; even if it be assumed that gastro-enterostomy largely prevents malignant changes, a percentage of the cases will be unknowingly malignant when operated upon. The cases of carcinoma included in this series were for the most part only definitely diagnosed microscopically after removal. The conclusions are: (1) that malignant change can occur in ulcer, although it is probable that the majority of carcinomata start de novo; (2) that a certain number of cases, apparently of ulcer, will be found definitely malignant upon microscopy. These are obviously arguments in favour of gastrectomy, but neither event is common, and I would not stress them.

FIG. 4.

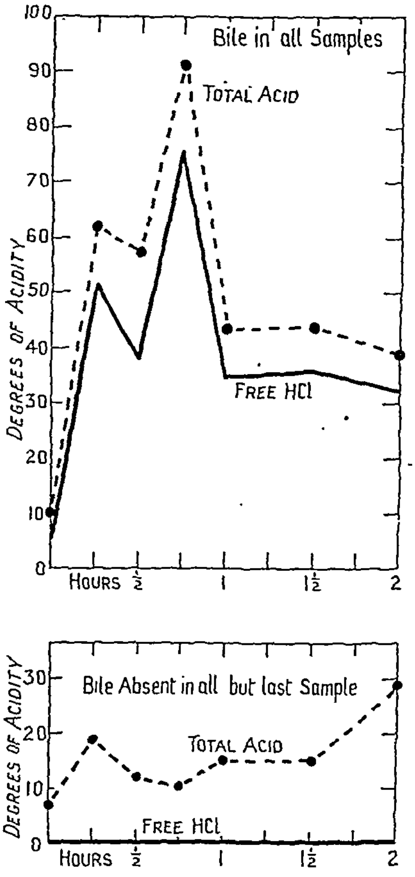


The lower curve (B) was taken a fortnight after partial gastrectomy, whilst the upper curve (A) was obtained two years later. It shows the permanency of the type of curve.

How Gastrectomy Acts.

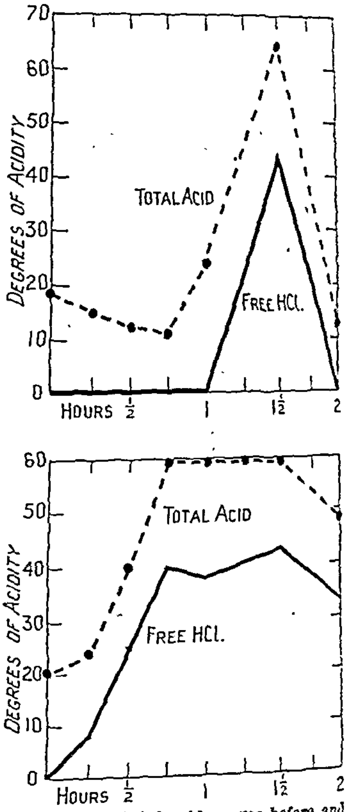
The limitation of ulcers to the pyloric region is marked, but not absolute, while the fact that jejunal ulceration occurs after short-circuiting shows that gastrectomy is not simply the removal of an ulcer-bearing area. Hyperchlorhydria has long been accepted as an important ætiological factor in the production of ulceration, and there is at least some association between the two. Accordingly it is assumed that gastro-enterostomy produces its effects by neutralising the acid with the alkaline contents of the jejunum. The post-operative test-meal curves show positively that there is an essential difference between the effects of partial gastrectomy and gastro-enterostomy. The gastro-enterostomies show merely a reduction in acidity (Fig. 5), while the gastrectomies reveal complete absence of free hydrochloric acid. This is not simply due to more effective neutralisation, for the total chloride is always very low in the absence of obvious bile or mucus (Fig. 3). This raises a point of some importance in the physiology of the stomach, for it can only be explained by assuming: (1) that the pyloric half of the stomach is the only portion capable of secreting acid—this is at variance with ordinary physiological teaching; (2) that the operation so profoundly modifies the general activities of the stomach, either by nervous reflex or locally, that the remaining cardiac half permanently ceases to secrete acid. Recent work upon the control of secretion, the secretion of neutral chlorides, and the effect of duodenal regurgitation has amply shown that the whole question is much more complicated than was *formerly believed; I hesitate, therefore, to draw* dogmatic conclusions upon what may easily prove to be inadequate data. Whatever the laboratory findings, *however, these clinical facts demand recognition and* critical examination. The fact that where the whole of the pyloric half was removed, no matter how much of the cardiac portion remained, *complete achlorhydria* resulted, while cases of limited pylorectomy (not included in this series) revealed in every instance merely reduction of acid, seems to prove that the results cannot be dismissed as erroneous or fortuitous. That the removal of varying amounts of the pyloric end would so consistently and permanently affect the secretion from the cardiac end scarcely appears feasible, but the rate of emptying of such a stomach is very rapid, and MacLean has recently shown that "the gradual decrease in acid concentration in the stomach during the completion of ordinary digestion in normal dogs is a function of the stomach itself, and in no way dependent upon regurgitation of alkaline duodenal contents." It may be that the absence of secretion is also an intrinsic "function" of the stomach when its general physiology is disturbed by the performance of a gastrectomy. A nervous reflex effect is excluded by the fact that sleeve resection, in which *the division of nerves is almost* as extensive as in the usual partial gastrectomy, is not followed by achlorhydria. The same applies in greater degree to definite denervation operations of which a typical post-operative curve is given (Fig. 6). The simpler suggestion—i.e., that the acid-*secreting portion is removed*—is probably the correct one. The physiological teaching with which this disagrees is chiefly founded upon experimental work on dogs, *the results of which should* only be applied with great reservation to human beings. The histological evidence of the presence of acidophile cells in the cardiac glands is also inconclusive, for it may be argued that the cytoplasm of a cell secreting acid would be left on the alkaline side of neutrality. The *intimate physiology* of these cells is not sufficiently understood for us to deduce the exact chemical changes which occur in the cytoplasm. A test-meal after partial gastrectomy is not without difficulties and uncertainties, and the *results may be due to the collection of material from* the jejunum rather than the remaining stomach. The characteristic curves given here, especially the effect of bile *upon the total* chlorides, and the general uniformity of results over a series of cases, suggest, however, that they are not the result of technical errors.

FIG. 5.



The upper curve was obtained 16 years after performance of posterior gastro-enterostomy, and shows that despite admixture of bile the free acid still remains high. At operation the pyloric ulcer was found to penetrate surrounding structures: the whole pyloric end of the stomach, including the anastomosis, was excised, and a fresh Polya type of anastomosis was performed to the cardiac end. *The lower curve shows the resultant achlorhydria, occurring despite absence of bile.* These curves demonstrate the profound difference between the effects of gastro-enterostomy and gastrectomy.

FIG. 6.



Free HCl and total acid curves before and after denervation of the stomach, showing no reduction in free acid but alteration in general character.

Those who believe that hydrochloric acid bears an ætiological relationship to ulceration find in this result a ready explanation of the success of partial gastrectomy. The growing school, however, who regard acid and ulcer as concurrent effects of an unknown cause will still be at a loss. On the whole, the evidence derived from these cases of gastrectomy is rather in favour of reinstating acid as an important ætiological factor which may, of course, be, and indeed probably is, itself secondary; for not only is the abolition of acid the most conspicuous result of the operation, but the *rarity of subsequent jejunal* ulceration is also best accounted for in this way. (Some believe that this result is due to the removal *with the original ulcer of the* possibility of infection of the suture line. As we have already seen, however, excision of the ulcer with *gastro-enterostomy is not followed by immunity.*)

The activity of pepsin is commonly ignored in considering the ætiology of ulceration, largely on account of the difficulties of quantitative estimation of enzymes, but it would probably be *more accurate* to use the term "*pepsin* hydrochloric acid" in place of plain "hydrochloric acid" throughout. The idea that the pyloric end of the stomach *is responsible* in man for the production of acid deserves the attention of physiologists. It certainly fits in *satisfactorily* with the division of the stomach into two functionally separate portions, a view supported to some extent by morphology and by radiology, the cardiac end being *considered* merely as a storehouse for food taken intermittently at meals, from *which the actively* digestive pyloric end is slowly and continuously supplied with pabulum.

Predisposing Conditions for Ulceration.

There has, in the past, undoubtedly been too great a tendency to think of gastric and duodenal ulceration as a local isolated lesion, a tendency which is reflected in the embolic theory and others where the microscopic anatomy of arterial distribution is held responsible. Careful examination of the ulcerated stomach or duodenum shows the great frequency of multiple ulceration, of the recurrence of ulceration at fresh sites, and of healed ulcers. These findings are especially important when founded upon the investigation of the parts removed by gastrectomy, or even better when seen in the live subject through a gastroscope (an instrument which the author has frequently used in these cases), for there can then be no suspicion of post-mortem effects. It is not going too far to state that almost all cases with prolonged histories afford evidence of multiple ulcers, either active or healed. We are not dealing with a lesion of local origin but with some condition of the stomach which predisposes to ulceration, and of which the ulcer itself is but a manifestation. The occurrence of jejunal ulceration after gastro-enterostomy for ulcer, and its absence after the same operation for carcinoma, favour the view that the contents of the stomach are responsible. The limitation of duodenal ulceration to the first portion, where it is exposed to the stomach efflux, may be also evidence (admittedly equivocal) of the importance of the contents. Yet the distinction between wall and content is not perhaps so great as it may seem, for the content is made up of two parts—the ingested food and the added secretion from the wall. The evidence given in this article, although incomplete, is in favour of a change in the contents as the exciting cause of ulceration, and this can conceivably be brought about (1) by changes in the nature of the secretion, and (2) by changes in the food taken. Once again we meet the relationship between pepsin hydrochloric acid and ulcer, for increase of acid secretion is the most constant and conspicuous change in the contents. Why a stomach should secrete these materials in excess is difficult to see; some authorities, on the evidence of test-meals, deny that they are in excess, but the ordinary test-meal only estimates the strength and not the quantities of acid secreted. When all the clinical and experimental work is examined it must be admitted that the association between the two is so close as to resemble cause and effect. Change in secretion, both quantitative and qualitative, is experimentally produced by alterations in the nature of the ingested food. The classical work of Pavlov showed that there is a psychical as well as a direct secretion, the former being stopped by nerve section. The importance of the psychical secretion in man is difficult to estimate, but it may be the secret of the alteration in gastric secretion. It is certainly intriguing, and perhaps not wholly fantastic, to assume that the flagging appetite of civilisation, with its sedentary occupations and economy of manual labour, is abnormally stimulated by the consumption of highly flavoured and spiced foods with the plentiful addition of condiments. These substances, including the extractives, are known experimentally to produce a copious psychical secretion of gastric juice. Pepsin hydrochloric acid may therefore be produced in large excess of that likely to be absorbed by the meagre quantity of food taken. The acid curves after the usual test-meal of gruel are not those which might be expected to follow the ingestion of a full meal, nor would it be at all easy to estimate the free acid in such a complicated mixture. Duodenal ulcer is said to be commoner among sedentary workers, and the symptoms are particularly prone to recrudescence during periods of mental strain and anxiety when the appetite fails; the same may be said of the symptoms attributed to hyperchlorhydria without ulcer formation. This theory assumes that the stomach is constantly being deceived into producing more secretion than is needed, and in the course of time develops the habit of excessive response. The success claimed for denervation operations may be partly due to the abolition of psychical secretion, although simultaneous cutting-off of the motor control and sensory supply renders definite conclusions impossible. The post-denervation test-meal curve given here shows little change, but of course it makes no pretence of representing the psychical secretion. If the habit of hypersecretion ultimately becomes an intrinsic function of the stomach denervation would produce little effect in established cases. So little is known, however, of the nervous control of the stomach in man and of the effects of denervation that it would be unwise to dogmatise.

Summary.

Ulceration should be regarded as a local incident in a much more fundamental general change in the functions of the stomach. This change, however produced, leads to the secretion of an excess of pepsin hydrochloric acid which may be regarded as the direct exciting cause of the ulceration. The acid may, in an uncertain and irregular fashion, be somewhat reduced by gastro-enterostomy; it can only be abolished by removal of the pyloric half of the stomach. Partial gastrectomy is the only operation which removes the cause of the ulceration in the majority of cases and which can be trusted to result in permanent cure. (Some may object to the use of this word when the affected part is excised.) This conclusion is amply borne out by the details given in this paper. The author has not quite enough courage in his convictions to subject to partial gastrectomy all cases of gastric and duodenal ulceration at whatever stage, but treats early cases upon medical lines in the hope that some change may thus be effected in the secretory activities of the stomach. In cases of simple duodenal ulceration of short history a partial gastrectomy appears unnecessarily severe when a safe gastro-enterostomy so frequently relieves the symptoms. This is perhaps not illogical, for in such cases the acid content is not always high and may therefore be sufficiently reduced by partial neutralisation. If the pre-operative test-meal reveals a high acid content it is probably wise, even in these cases, to perform a partial gastrectomy and so escape further ulceration, perhaps in the jejunum. For all other cases partial gastrectomy is the operation of choice, and, if the presence of adhesions, penetration of ulcer, or difficulty of access will obviously render the operation a difficult and dangerous one, the possibility of anastomosis of jejunum with the cardiac half of the stomach and the resection of the pyloric end at a subsequent operation, as in the Billroth 2 method, should be seriously considered. In this way an operation, otherwise serious, may be rendered comparatively safe. Where gastro-enterostomy has already been performed without relief of symptoms, partial gastrectomy holds out a very good hope of cure; indeed some of the most gratifying cases in the series come into this group. In the absence of jejunal ulceration it is sometimes possible to utilise the gastro-enterostomy aperture, the pyloric end being excised as in the Billroth 2 operation. Where the original anastomosis has been performed towards the pyloric end, or where jejunal ulceration is present, the whole is excised with the stomach and a fresh anastomosis made, usually by the Polya method. The former is a very safe procedure, but the latter may in some difficult cases demand the utmost dexterity and care.

Ulcers in the cardiac half of the stomach are not so uncommon as is sometimes thought. Where the ulcer is capable of local excision, without danger, this should be done, combined immediately or subsequently with partial gastrectomy. Where the ulcer cannot be excised removal of the pyloric end is nevertheless indicated. This method of treatment has been adopted in several cases with complete relief of symptoms, and definite radiographic evidence of cure of the ulcer.

No reference has been made to the actual cause of the pain, since this is outside the scope of the article. If, as is probable, it is due to irregular muscle tension and abnormal intragastric pressure (in the absence, of course, of penetration of surrounding structures), a partial gastrectomy must correct both, as it produces immediate relief of symptoms. Relief of symptoms, however, does not necessarily imply cure of the ulcer, as shown by the cases of hæmorrhage and perforation which occur after gastro-enterostomy has produced complete relief of symptoms. For this reason special emphasis has been laid here upon the actual cure of ulceration and prevention of recurrence rather than upon the mere relief of symptoms.

I wish to acknowledge my indebtedness to Mr. E. Crook, surgical registrar, Charing Cross Hospital, who has taken infinite pains in the collection of the statistics and the carrying out of post-operative inquiries; to the staff of the Institute of Pathology for their chemical (Dr. J. Patterson) and pathological (Dr. A. B. Rosher and Dr. Berry) investigations, and to Dr. Russell Reynolds and Dr. Cochrane Shanks for the radiographic work.

THE STANDARDISATION OF SCARLET FEVER ANTITOXIN

BY CLINICAL METHODS.

BY ROBERT CRUICKSHANK, M.D. ABERD., D.P.H.,

MCROBERT RESEARCH LECTURER, UNIVERSITY OF ABERDEEN; FORMERLY ASSISTANT MEDICAL OFFICER, BELVIDERE HOSPITAL, GLASGOW.

THERE are four methods in use for the standardisation of the scarlatinal streptococcic toxin and antitoxin. Three of these are clinical tests for which the human volunteer is necessary; the fourth is a method, recently described by Parish and Okell, which tests the potency of scarlatinal antitoxin in protecting rabbits against the intravenous injection of whole cultures of *Streptococcus scarlatinæ*. Laboratory animals are relatively insusceptible to the toxin of *S. scarlatinæ*, and this last method, while it serves to "differentiate efficient therapeutic sera from inefficient," lacks the accuracy with which the dosage of diphtheria antitoxin, for example, may be estimated. Whereas 0·002 c.cm. of diphtheritic toxin is an average lethal dose for a guinea-pig, 20–40 c.cm. of scarlatinal toxin, representing 500 times the quantity of toxin which will produce the scarlatinoid syndrome in man, are required to kill a rabbit. Nevertheless, any laboratory method which may compete in accuracy with the clinical tests for the standardisation of scarlatinal antitoxin must be the method of choice for various reasons. The tests can be carried out by competent technicians in the laboratory where the toxin and antitoxin is being prepared; the supply of animals is not limited like the number of human volunteers, and the individual variability is probably much less in the rabbit than in man.

The three clinical methods by which standardisation of scarlatinal antitoxin may be attempted are: (1) by the utilisation of the Schultz-Charlton phenomenon; (2) by passive immunisation; and (3) by the so-called skin method. It is proposed to give a short description and discussion of the results obtained from the use of these methods, and to discuss shortly their relative merits and limitations.

The Schultz-Charlton Test.

The serum of an individual convalescent from scarlet fever, or artificially prepared scarlatinal antitoxin, injected into the skin of scarlet fever patients while the rash is still bright, causes a blanching of the skin at the site of injection. In the application of this phenomenon to the diagnosis of scarlet fever (using a 1 : 10 dilution of antitoxin) a positive reaction is evidence of scarlatina, but a negative result does not quite exclude the infection, since some scarlet fever rashes are not blanched. Moreover, the test is least reliable where its use is most indicated—namely, in faint and otherwise atypical eruptions. It has, however, a useful application in the standardisation and comparison of scarlatinal antitoxins.

Method.—In the performance of the test dilutions of 1 : 1000 to 1 : 32,000 of the sera were used, since an antitoxin which does not cause blanching in a dilution of 1 : 1000 is of little therapeutic value. Children of 5 to 15 years with bright finely punctate rashes gave the best results; the abdomen is the most suitable site for the tests, and 0·4 c.cm. of the serum dilution was found to be an appropriate dose for injection. Usually four tests were done on each patient: two different antisera were compared, and two dilutions of each were used. If, for example, a dilution of 1 : 4000 but not 1 : 8000 of antitoxin A causes blanching, and a dilution of 1 : 8000 of antitoxin B causes blanching, the antitoxins can be standardised, and it is established that serum B has double the therapeutic value of serum A. Two sera S.A. 4571 and S.A. 4462 in dilutions of 1 : 1000, 1 : 8000, and 1 : 16,000 were tested. Antitoxin S.A. 4571 gave uniformly positive reactions in dilutions of 1 : 1000 and 1 : 8000, but two only out of eight cases tested were positive with a dilution of 1 : 16,000. S.A. 4462 produced blanching in a dilution of 1 : 1000 with all cases, but only four out of sixteen and none out of eight patients when tested with dilutions respectively of 1 : 8000 and 1 : 16,000 gave positive reactions.

Passive Immunisation.

To standardise and compare antitoxins by the passive immunisation of susceptible subjects one of two methods may be adopted: either (*a*) find the smallest dose of antitoxin which will render a Dick-positive reaction Dick-negative in 24 hours in a patient accidentally exposed to the risk of infection; or (*b*) determine the duration of immunity conferred by the injection of a standard amount of the antitoxin. The second method was used: 2·5 c.cm., 5 c.cm., *and in a few cases 10 c.cm. of the serum* was injected intramuscularly into patients who had given definite Dick-positive reactions; these individuals were then Dick-tested at regular intervals of time (24 hours, 5, 8, 13 days), until they again became Dick-positive. For comparison of the two antitoxins, the test-subjects were as far as possible children of the same age, giving Dick reactions of equal intensity. Even then, a lack of uniformity in the results may be expected, for the amount of scarlatinal antitoxin already present in the blood is probably not the same for any two individuals. For instance, the injection of 5 c.cm. of antitoxin may protect one child for two weeks, while an equal amount of the same antitoxin may protect another child with less natural antitoxin for one week only.* Table I. briefly summarises the results obtained.

TABLE I.—*Duration of Immunity with* (A) *2·5 c.cm. and* (B) *5 c.cm. Antitoxin.*

	12 „	16	0		13 „	11	3
					17 „	14	0

The Skin Method.

The test subjects for this method of standardisation must be, as in the passive immunisation method, susceptible to scarlet fever, and must give a Dick reaction of at least 20 mm. diameter with five skin-test doses of toxin. In hospital, patients convalescent from diphtheria and chicken-pox, and accidentally exposed to the risk of infection, were found most suitable for the purpose.

---

* *The utility of passive immunisation in affording immediate protection to susceptible individuals exposed to scarlet fever* has been discussed elsewhere (Cruickshank, Glasg. Med. Jour.). It may be said that in general 2·5 c.cm. of a concentrated antitoxin protects for 3–6 days, 5 c.cm. *for* 7–10 days, and 10 c.cm. *for 2–3 weeks.*

Method.—Measured volumes of the toxin diluted to contain ten skin-test doses in 0·2 c.cm. were mixed in vitro with equal quantities of antitoxin in dilutions of 1 : 100 to 1 : 1000. After standing at room temperature for one hour, 0·2 c.cm. of these toxin-antitoxin mixtures—each containing five skin-test doses of toxin—was injected intradermally; a control test with toxin alone was also done. The mixture which reduces the reaction from 20 mm. in size to less than 10 mm. contains sufficient antitoxin to neutralise five skin-test doses of toxin. The "therapeutic dose"—the amount of antitoxin required to neutralise 20,000 skin-test doses of toxin (Dick and Dick)—can be readily calculated. Two sera, S.A. 4627 and S.A. 4565, were compared. The preliminary dilutions were made with graduated 1 c.cm. pipettes, a separate pipette being used for each antiserum and for the toxin, and again separate syringes were used for the intradermal injection of the different mixtures. The abdomen is the site of choice, since half a dozen or more tests can be done simultaneously and the reactions are more definite and measurable there than on the arms.

The results given in Table II. indicate that the "neutralising" dilution of antitoxin is 1 : 100.

TABLE II.—*The Skin Reaction to the Intradermal Injection of Toxin plus Varying Dilutions of Antitoxin.*

Size of Reaction in mm. Measured in Two Diameters.

Dilution of antitoxin.	S.A. 4627.		S.A. 4565.		Toxin control. 24 hrs.
	24 hrs.	48 hrs.	24 hrs.	48 hrs.	
1 : 1000	26 : 31*	30 : 33	16 : 20	25 : 25	32 : 40
1 : 800	17 : 23*	17 : 17	14 : 17	17 : 19	21 : 26
1 : 400	15 : 23*	18 : 23	10 : 13	15 : 21	24 : 27
1 : 200	14 : 17*	22 : 25	11 : 16	17 : 17	34 : 37
1 : 100	—	15 : 15†	20 : 22†	20 : 25†	27 : 33

* Each of these figures represents the average of four separate reactions on four children.

† With 1 : 100 dilution of antitoxin only one case showed any reaction with both S.A. 4627 and S.A. 4565.

Discussion.

None of the three clinical methods under consideration gave results that were sufficiently delicate and uniform to merit recommendation as an accurate and reliable method of standardising scarlatinal antitoxin. This might a priori be expected, since the human subject varies within wide limits in his response to infection; the variation, where scarlet fever is concerned, is probably due, in part at least, to the variable amount of natural antitoxin in the blood of different individuals. The difficulty could be surmounted by taking the average of a large number of individuals, but unfortunately the supply of human volunteers is limited.

In a comparison of the tests, preference must be accorded to that method which is the most delicate and at the same time gives uniform results. In other words, a method which will distinguish between the neutralising power of dilutions of 1 : 100 and 1 : 200 of an antitoxin, or between the antibody content of 2·5 c.cm. and 5 c.cm. of a serum, is preferable to a method which can only tell us that a dilution of 1 : 100 is more potent than one of 1 : 400 or 1 : 800, or that 10–20 c.cm. of a serum contains more antibody than 2·5 c.cm. The tables show that the results obtained by passive immunisation best fulfil the requirements, provided that the Dick test be repeated at four- to five-day intervals. Taking antitoxin A.4162E (Table I.). for example, if the patients were Dick-tested only 24 hours after injection of the serum it would be impossible to distinguish between the protective values of 2·5 c.cm. and 5 c.cm., but eight days afterwards, 14 out of 16 individuals receiving 2·5 c.cm. were again Dick-positive, compared with four only out of 14 receiving 5 c.cm. of antitoxin. Unfortunately the passive immunisation method requires a prolonged observation of the test subjects with repeated Dick tests, and, in addition, the injection of serum, which may not be without attendant risks in a sensitised individual. The Schultz-Charlton test can be carried out only on patients with bright scarlatinal rashes. Apart from the small percentage of cases which fail to react to the test, the method gives results which are fairly uniform and delicate.

The skin method, in our hands, failed to differentiate a dilution of antitoxin of 1 : 800–1 : 1000 from a dilution of 1 : 200, so that on the standard of delicacy it failed. The method has certain advantages, however, in that it is fairly easy, the tests are done on susceptible subjects, who require to be under observation for two days only, and the results obtained were more uniform and clean-cut than with either of the two previous methods. It is the method recommended by Dick and Dick, and has been adopted as the official method of standardising scarlatinal antitoxin by the Hygienic Laboratory of the United States Public Health Service.

If these clinical tests be compared with the laboratory test of Parish and Okell, they appear to have some advantage in the differentiation of the relative therapeutic values of scarlatinal antitoxins, but the drawbacks to the clinical tests are such as to give the laboratory test the preference as the method of choice. It must not be supposed, however, that any of the methods at present available is sufficiently accurate to allow a uniformity in the dosage of scarlatinal antitoxin in any way approaching that of diphtheria antitoxin.

I am indebted to Dr. R. A. O'Brien, of the Wellcome Physiological Research Laboratories, for suggesting this piece of work and for advice throughout its course. Most of the material was supplied directly by him.

ÆTIOLOGY OF HYPERPIESIS IN EGYPTIANS.*

BY ABD-EL-AZIZ ISMAIL, M.R.C.P. LOND.,
D.P.H. LOND., D.T.M. CAMB.,
PHYSICIAN, KASR-EL-AINI HOSPITAL, CAIRO.

THE conclusions in this paper are based on a study of over 3000 cases, many of whom were traced for 10 to 15 years. All were seen in private practice, so that they were observed over a much longer period than is possible in a hospital; observations for short periods on a disease which seems to be lifelong are misleading, and give a false idea of its natural course.

Chronic primary hyperpiesis in the absence of chronic inflammatory renal changes is quite common in Egypt, and forms at least 10 per cent. of all cases in private clinics, but is rare in hospital practice. For four years, 1913–1917, not a single case was admitted, and in the following years only two genuine cases could be picked out. The disease is especially limited to the two decades 35–55, and is very rare under 30; the youngest patient was a student of 27 whose father and mother had both suffered from the disease, which appeared in him when he was 23. The condition is rare after 60, and the eldest patient was about 75. About 10 per cent. of the cases are females.

Out of 100 consecutive cases 37 were fellahin of the middle class, 17 were lawyers, judges, and mental workers, 10 were doctors, and 10 females; the rest came from clerical and other occupations, two being railway porters.

---

* Summary of several addresses given to Kasr-el-Aini Hospital Society and Egyptian Medical Society.

Diet, Nervous Influences, Toxins, and Infections.

That excess of food, especially protein, causes a hyperpiesia is undoubted. The rise is, however, temporary, and the pressure falls gradually and sometimes suddenly as soon as the intake is limited.

A young man of 30, weighing 72 kilos, developed pulmonary tuberculosis and was advised to over-feed. His blood pressure rose from an average of 100/75 to 200/100, and remained up for about six months, during which time his weight increased by 25 kilos. With limitation of diet and graduated exercise the pressure fell to 150/105 in the course of three months, and has remained there till now (three years).

Excess of diet plays a part in acute hyperpiesis in normal subjects or in extra rises (often temporary) in subjects of chronic hyperpiesia. That diet is certainly not the cause of the latter is shown by the fact that 40 per cent. of cases of high hyperpiesia were of normal weight or slightly under. Overfeeding and overweight is by no means always accompanied by rises of pressure, and in women of a certain class, especially at the climacteric, though overweight is common, less than one-fifth have hyperpiesia.

That strong emotional disturbance can cause marked rises of pressure is certain; the effect is, however, temporary, and in no single case was a permanent effect found.

A lady of about 50, previously in good health, with systolic pressure ranging from 120–140 for years, suddenly, after prolonged grief, complained of severe headache, congestion of the face, and asthmatic-like attacks at night. Blood pressure 310/160. No sign of local nerve lesion. Urea 30 mg. or 0·03 per cent. of blood; urine normal. Venesection and elimination treatment with bromides lowered the pressure to 200/100–240/110 in about six days, but the systolic pressure remained about 200 for at least two months in spite of treatment. On separation from her husband (apparently a great mental relief) the pressure fell to 120–150, and for the last year and a half there has been no return to the high figure.

Many similar cases were observed, and in all of them the pressure fell as soon as the nervous condition improved. Nerve storms are important causes of rise of pressure in normal subjects, of extra rises in hyperpietic cases, or even of onset. That they are not the sole cause is shown by the fact that fully one-third of the cases occurred in placid men and women of the middle class with sedentary habits, many of them unable to read or write and having no special complaint. Conversely, hyperpiesia does not necessarily follow emotional states.

That certain substances absorbed from the alimentary tract have a pressor action has been shown experimentally, and some—e.g., isoamylamine, P-hydroxy, phenylethylamine, and phenylethylamine—have been isolated. These and similar substances may be operative in acute cases of hyperpiesia, as shown by the rapid fall of blood pressure (often permanent) on elimination treatment and starvation. In chronic primary hyperpiesia the blood pressure is affected very little if at all by any method of treatment. Formerly, hyperpiesis was looked upon as an untoward sign in all cases, and every effort was made to lower it, including rest in bed for months at a time, repeated venesection, repeated doses of calomel and salines, and strict lacto-vegetarian diet with two starvation days per week. It soon became clear that the resulting fall was slight, and in some cases the pressure actually rose during the treatment—showing conclusively that the rise was not due to absorbed toxins, the amount of which should have been diminished by a very restricted régime.

A railway inspector was seen on several occasions in 1919 with average blood pressure 170/80 and nervous symptoms (fatigue and insomnia) suggesting neurasthenia. With absolute rest in bed and milk diet the symptoms markedly improved, but the blood pressure rose to 220/100. The patient remained in perfect health, and for the next three years his pressure ranged from 200–220. Since then nothing has been heard of him.

The course taken by chronic hyperpietics is a continuous one with few intermissions (extra rise or fall), which would certainly not be the case were the rise due to absorption of toxins, the amount of which would be subject to continuous variations. Again, toxins, whatever their nature, would give rise to other symptoms besides hyperpiesis, but these patients continue generally for years without any symptoms at all; some have been traced for 15 years and some, with a reliable medical history, for 25 years. Occasional symptoms, such as headache, giddiness, dyspnœa, or asthmatic attacks, can be easily shown to have no relation to the chronic malady. They bear no relation to the degree of hyperpiesis, and often occur without extra rise of the blood pressure, and in some with a relative fall. They can be relieved by eliminative treatment, which does not affect the height of the blood pressure, for this is in many cases higher after treatment than before. These symptoms are due to absorption of substances with a pressor or a depressor effect, and have no relation to the original disease.

An example is afforded by a patient with severe headache following trephining for chronic glaucoma, unexplained by the eye condition. The blood pressure varied from 220/110 to 230/130, and remained approximately at the same height for six weeks; with blood-letting, elimination, and starvation it dropped at times to 200, but the headache did not disappear. Finally the headache disappeared spontaneously, but the pressure has remained at about 240/140, with occasional rises, until now (2½ years).

Graver and more permanent symptoms which occur in hyperpietics are due to arterio-sclerosis or its complications, and not directly to the hyperpiesis. Much, however, may be said in support of the view that arterial disease is secondary to the increased pressure.

Syphilis, at times suspected as a cause, certainly has no relation to the disease; repeated courses of bismuth, mercury, and arsenic will change a positive Wassermann to negative without changing the pressure. Temporary rises of pressure occur in syphilitic subjects, as in normal subjects, but that has no relation to the chronic malady.

A history of old infectious fever (typhoid, malaria) is quite common, but so high is the incidence of both the infectious fevers and hyperpiesia that no causal relation between them can be established. A notable feature is the absence of ankylostoma and pellagra, and, to a lesser extent, of bilharzial infection, diseases which are very common in hospital class patients, in whom hyperpiesia is almost non-existent.

Alcohol as a cause can easily be dismissed, as the majority of patients had never tasted it. Tobacco seems to lower the tension, and some of the marked hypotensives were heavy smokers (over 40 cigarettes daily). Excess of coffee seems to be responsible for temporary rises of pressure in normal individuals and hyperpietics. No causal relationship can, however, be drawn between the amount of coffee taken and the degree of hyperpiesis. Some of the marked hypotensives were patients who consumed 40 cups daily (4·0 g. caffeine) for years, and fully one-third of all cases of hyperpiesia drank no coffee, or less than 10 cups daily (1·0 g. caffeine).

The Family History.

The disease is hereditary and social, and in many cases familial. In 100 consecutive cases 72 had a history in the father or mother, brothers or sisters, uncles or aunts, suggesting death from one of the complications of the disease—e.g., a hemiplegia or death suddenly after a meal (angina pectoris) or an attack of dyspnœa or fatal epistaxis. This generally occurs in the fifth and sixth decade, and is well known amongst the middle class, who are the chief sufferers, and often a man will come for examination for no other complaint than that his father or mother died from or was affected with hemiplegia.

In some cases notable family histories occur—e.g., a merchant in Upper Egypt (Mallawy), aged 55, seen a year ago. His blood pressure ranged from 180/100 to 200/120. His father died about the age of 60 with coma and hemiplegia; his mother died, when over 60, with hemiplegia. Three brothers, aged respectively 50, 48 and 44, all showed pressures between 160 and 200 on several occasions.

Another marked example was that of a merchant affected with the disease, whose father, mother, two sisters, and four brothers were all affected (except one brother who had rheumatic endocarditis).

As a control the family history of 100 consecutive cases of other ailments was taken, and only 25 per cent. gave a history of father or mother being affected with symptoms suggesting hyperpiesia.

The Relationship between Hyperpiesis and Diabetes.

In families where only one member is affected with hyperpiesis, a clear history of diabetes is often given, and sometimes some members of a family are affected with diabetes, some with hyperpiesia, and some with both. The relation between diabetes and hyperpiesis is very close. Both are diseases of the middle and upper classes, and very rare in the poor-class hospital patient. Both run a very long course, and for years there may be no symptoms in the absence of complications. The chief age of onset in both diseases is from 30–40, and the duration of both is approximately the same. The majority of hyperpietics die in the 'fifties and 'sixties; diabetics, having better treatment, generally die in the 'sixties or 'seventies. The age of onset and duration account for the rarity of hyperpiesia above 65 and of diabetes above 75. Amongst several thousands of hyperpietics seen in 15 years I can only recall nine cases above 65, including two between 70 and 80. The same statement holds good for diabetics, if allowance is made for slightly increased longevity. Both diseases run their course in spite of any treatment. This is certainly true of hyperpiesia, and was true of diabetes before the days of insulin and regulated diet. Except in acute crises treatment of hyperpiesia is useless, and at times dangerous; the rise of pressure is certainly compensatory. Attempts to lower the pressure by venesection, elimination, vaso-dilators, diet, &c., were in the majority of cases unsuccessful, and in those in whom it was lowered temporarily symptoms arose (cerebral, renal or cardiac), apparently due to the anæmia which only disappeared on resumption of previous habits. The patient has to choose between a slightly prolonged and restricted life and a useful, apparently normal, short one, often terminated suddenly by fatal cerebral hæmorrhage, angina or uræmic-like symptoms. I certainly do not agree with Clifford Allbutt when he says: "If we catch hyperpiesis early and keep at work against it, it can be cured more often than not."[1] Hyperpietics who do not die from complications end with uræmic-like symptoms of auto-intoxication, analogous to diabetic coma. The similarity is so great that I surmise that hyperpiesis is due to a metabolic disturbance (dyscrasia), often inborn and hereditary. Nothing is known about the relation of this disorder to ductless glands. A full trial of thyroid and parathyroid was made for months, and sometimes for years, in suspected cases, and the results, though encouraging in a small number, can only relate less than 2 per cent. of all cases to deficiency of internal secretions. One thing seems certain, and that is the relation of the hyperpiesis to the metabolic change; the rise of pressure is entirely compensatory, and as long as the pressure is relatively sufficient no symptoms arise, and the individual enjoys normal habits. Only when the pressure begins to fall do symptoms appear referable to the metabolic dyscrasia.

WESTERN OPHTHALMIC HOSPITAL, MARYLEBONE, AS A "DANGEROUS STRUCTURE."—This hospital has been served with a "dangerous structure" notice by the district surveyor of Marylebone on the ground that the building "might collapse at any moment like a house of cards," and its demolition has been begun. Great difficulty has been experienced in finding accommodation for the patients, 18 of whom are awaiting operation. The hospital is an old Georgian building in the Marylebone-road, very cramped and inconvenient, with wards the size of small bedrooms. The operating theatre is only a few feet square with a floor of rough boards, and a roof which leaks in wet weather; there are no facilities for moving patients after operations. A rebuilding scheme to cost £10,000 was prepared some time ago, and £23,000 has so far been collected.

Clinical and Laboratory Notes.

A NOTE ON
BLOOD CHANGES ASSOCIATED WITH LIVER DIET IN YOUNG CONVALESCENTS.

By K. SHIRLEY SMITH, M.B., M.R.C.P. LOND.,
MEDICAL REGISTRAR, MIDDLESEX HOSPITAL;
AND
L. E. H. WHITBY, M.D. CAMB., M.R.C.P. LOND.,
ASSISTANT PATHOLOGIST TO THE HOSPITAL.

IN order to find out whether the blood changes obtained with liver diet in cases of pernicious anæmia were confined only to that disease, it has been thought worth while to study the blood changes produced by the same diet in hospital patients free from any blood disease. Whereas the original work of Whipple indicated that liver diet was likely to be useful in all forms of anæmia, the first recorded results with liver diet in pernicious anæmia suggested that it was most specific for pernicious anæmia and exerted its maximum effect only in that disease. Recently it has been found by Vaughan[1] and others that some cases of secondary anæmia respond to liver treatment, and we have found that relatively normal children show a transient but definite stimulatory response to liver feeding.

The 11 cases selected for treatment in this investigation were between the ages of 3 and 15 years with the single exception of one girl aged 19. The majority of the patients were in surgical wards and were, during the experimental period, convalescing from such surgical conditions as inguinal hernia, tuberculous adenitis, and submaxillary abscess; others were in medical wards under treatment for such diseases as mediastinal adenitis and oxaluria. On account of the special interest attaching to the blood changes observed in them two cases are included in which the lymphatic system seemed principally affected; these were cases diagnosed as Hodgkin's disease and glandular fever.

Fresh cooked liver was given daily, the amount varying with the age of the patient; the older patients received 3 oz. daily and the younger ones 2 oz. A blood examination was made in every case before starting the diet and the feeding was continued for periods varying between six and 40 days. In the first few cases examinations were made at intervals of three or four days for a period of three weeks, but experience showed that the maximum effect was noticeable after about six days and that it declined thereafter. In no case was hæmatinic drugs given during the time of liver feeding.

The table shows the results with the 11 patients. In most cases the changes in red and white cell counts and in the hæmoglobin percentage have been included, whilst the alteration in the differential leucocyte count are recorded in all. The last two columns show the variations in the granular and non-granular cells in order to contrast the changes in bone-marrow cells with those taking origin from some source other than the bone-marrow. Such observations as were made on the red cells and hæmoglobin show that these tended to increase. A leucocytosis was produced in seven out of the 11 cases. In seven cases also there was an increase in the relative and absolute number of polymorphonuclears. Neither the increase in the total leucocytes nor the increase in polymorphonuclears was maintained for longer than ten days. Lymphocytes showed a relative but not absolute reduction in nearly all cases. A definite absolute increase in eosinophils was produced in all instances, the striking figure of 61 per cent. being found in the case of Hodgkin's disease. An increase in granular or bone-marrow cells was also the rule.

---

[1] Vaughan, Janet: THE LANCET, 1928, i., 1063.

These results show that the administration of liver to patients who suffer neither from pernicious anæmia nor any other blood disease produces alterations in the blood comparable to those occurring in the treatment of pernicious anæmia. An interesting feature of the series is the eosinophilia which has been also found in pernicious anæmia by one of us (L. E. H. W.),[2] and in secondary anæmia by Vaughan.[1] The definite increase in the red cells and bone-marrow leucocytes shows that liver must exert a stimulating action on the bone-marrow. It is difficult to believe that stimulation is the only action in pernicious anæmia though evidently it is one essential feature.

We are inclined to suggest that liver is rich in a substance essential for the proper functioning of the bone-marrow; in pernicious anæmia, this substance, whatever it may be, is not absorbed in sufficient quantity from an ordinary mixed diet, perhaps on account of the achlorhydria, though it is possible to assimilate enough with massive liver feeding.

[2] THE LANCET, 1928, i., 285.

A COMPARISON OF THE "TITANIUM RAY" WITH THE METALLIC TUNGSTEN ARC.

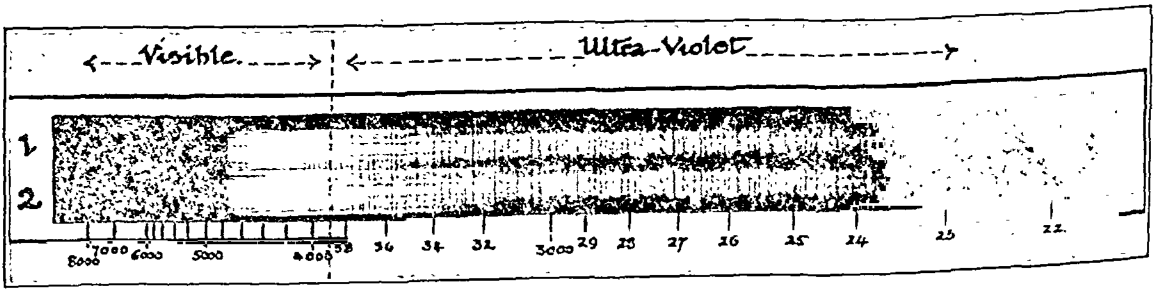
BY B. D. H. WATTERS, M.Sc.

(*From the Physics Department, Middlesex Hospital.*)

CONSIDERABLE interest has been aroused recently by a new arc designed for therapeutic work which is termed the "titanium ray." The arc is formed between metallic electrodes which consist of a tungsten alloy containing, it is claimed, approximately 4 per cent. titanium.

Titanium is a rare metal which occurs in small quantities in a large number of ores, and hence is often present in different metals as an impurity. The characteristic arc spectrum of the metal has a number of intense lines in the ultra-violet region. Samples of the electrodes supplied for generating this arc were obtained and the arc spectrum tested by means of a Hilger quartz spectrometer. For purposes of comparison, the spectrum given by metallic tungsten of the quality used in therapeutic work was included on the same plate. The photograph of the two spectra is shown in the illustration, and it will be seen that they are practically identical both in the range of the ultra-violet and the distribution of the intensity. Detailed examination of the plate under a low-power microscope shows certain minor lines as more intense in the "titanium ray" spectrum than in that given by commercial tungsten. These variations are, however, so slight that the difference in the quality of the radiation from a therapeutic point of view must be considered as negligible.

The print reproduced here was obtained from a single plate containing the spectra of the two sources. An incandescent filament lamp was used for printing and the distance of the lamp from the plate was adjusted so as to bring out the full range of the radiations.



The upper spectrum (1) is that of the "titanium ray" and the lower (2) is that of the tungsten arc. Exposure in each case 30 seconds. (Photographed on an Ilford Process Plate.)

A further test was made of the intensity of the radiation from the two arcs judged by the production of erythema on the skin. Two small areas of skin close together on the forearm were exposed consecutively to the arcs running under identical conditions as far as could be done. (Current, 6 ampères; P.D. across electrodes, 58 volts; voltage of supply drawn from a bank of large accumulators, 120 volts.) Three distinct pairs of exposures were made on different days and in each case the erythema produced by the "titanium ray" and the tungsten arc could not be distinguished in depth of coloration and the latent period between the exposure and the appearance of the reaction was the same.

It has been stated that the "titanium ray" is more penetrating than other sources of ultra-violet light, but, judging from the evidence of the experiments described above, the penetration of the radiation can be no different from that of other sources with a similar spectral distribution.

A CASE OF

ABSCESS OF THE HEART CAUSING DEATH THROUGH CORONARY HÆMORRHAGE.

By Francis McLagan, M.B. St. And., D.P.M.,
ASSISTANT MEDICAL OFFICER, CANE HILL MENTAL HOSPITAL, SURREY.

A case of abscess of the heart apparently resulting from staphylococcal infection of the skin, and without evidence of general pyæmia, is so rare that its description seems to be justified. Not only is the occurrence uncommon, but in the case reported death was due to rupture of the abscess into one of the coronary arteries and the pericardial sac, giving rise to a condition which simulated, and was at first mistaken for cardiac rupture.

The Case Described.

A married man, aged 57, was admitted to hospital under certificate on Jan. 30th. Previous to certification he had been in poor health for some time and his latest occupation had been the somewhat arduous one of labourer. During his multifarious pursuits—principally as soldier and stoker—he had contracted malaria in Upper Burma and suffered from sunstroke in India many years previously. His condition on admission, however, was not thought to be consequent on these misfortunes. His personal history, as related by his wife, showed him to be a man of temperate habits who, four years previous to admission, became weak, was subject to numerous boils and carbuncles, and developed tremors of the legs.

On admission he exhibited many old scars, the result of boils and carbuncles in the region of the back and legs, but only one scar on the upper part of the body, and that on the right shoulder. His chest was fairly well covered, but the excursions on respiration were limited. No abnormality of the lungs was apparent on percussion, but on auscultation râles and rhonchi were heard to such an extent that the heart sounds were obscured. The apex-beat was 2 in. outside the nipple line, and the left border of the heart was found in a corresponding position. His arterial system, as judged from palpation of the radial artery, exhibited marked atheromatous and senile changes. He was very unsteady on his legs and walked with a very wide gait, and on examination of his reflexes it was found that his knee-jerks were very brisk and exaggerated.

As the mental disturbance has no bearing on the point under consideration, a detailed account of his psychosis can be omitted. It is considered only sufficient to state that although his memory was greatly impaired, he suffered from no delusions or hallucinations, and he was capable of appreciating pain or distress and communicating his sensations to those in attendance.

On Feb. 18th he developed a large carbuncle over the right trochanter, was put to bed, and received appropriate treatment in the form of free drainage. The carbuncle responded well to treatment, but three days later (Feb. 21st) a boil appeared on the left hip. This, however, had healed by March 7th, but the original area, although clean, had not closed. On March 12th another carbuncle appeared on the right buttock and several others appeared in a few days in the region of the hips, buttocks, and sacrum. On the evening of March 30th the patient conversed as usual with the medical officer and complained of no unusual symptoms, but at 12.5 A.M. on the following day it was reported that he seemed to have had a "seizure" and had collapsed. When seen by the medical officer he was found to be in extremis, and despite treatment he died at 12.20 A.M.

The Wassermann reaction of the blood and cerebrospinal fluid was negative.

Post-mortem Findings.

At autopsy marked atheroma was apparent in all areas of the body with consequent cerebral softening; enlargement of the cerebral ventricles and increased submeningeal fluid. The heart was enlarged, weighing 530 g., and showed marked myocardial hypertrophy with fatty degeneration; these latter pathological changes were most apparent in the left ventricle. The cardiac valves appeared normal, apart from slight atheromatous changes, and gave no evidence of vegetations or acute inflammation. The pericardial sac was filled, but not distended, with a soft blood-clot and a small tumour in the region of the great vessels. The tumour formed a small protuberance ½ in. in diameter and projected about ¼ in. from the surrounding heart wall. It was found on examination to be softer in consistency than the normal muscle, and one small channel was discovered through which a probe could be passed into the right coronary artery ½ in. from its origin in the sinus of Valsalva. On making a cross-section of the growth a loculus was encountered containing about 1 c.cm. of pus; unfortunately, no culture media was at hand and the nature of the causative organism remains in doubt.

All the other organs of the body were carefully examined and no evidence of pyogenic infection was discovered other than the cutaneous lesions already described, and pyorrhœa alveolaris. The viscera, apart from the lungs which were passively congested, showed degenerative changes subsequent to the impaired blood-supply brought about by the atheroma.

It is presumed that the condition was one of multilocular abscess (carbuncle) of the heart wall in which the pus had tracked, in one of the loculi, in two directions—to the coronary artery and to the pericardial surface of the heart. In this manner a channel had been formed through which the blood had flowed into the pericardial sac, producing a mechanical resistance to an already greatly weakened heart and so caused death.

I wish to express my thanks to Colonel S. C. Elgee, medical superintendent of Cane Hill Mental Hospital, for permission to publish this case.

Public Health Services.

THE HEALTH OF LONDON IN 1927.

Dr. F. N. Kay Menzies, in his report on the County of London for the year 1927, explains that in recent reports the general public health services have been extensively dealt with, and that in the present instance he has devoted more attention to the school medical service, which, "joining hands with social agencies, is more intimately in touch with the domestic lives of the people, and in this way exercises a material influence on the general public health."

General Health Services.

Statistics.

The Registrar-General's estimate of the population was 4,550,000, including 9000 non-civilians. The 73,263 births gave a birth-rate of 16·1 per thousand. In 1901, when the population was about the same, the births were 57,829 more. The death-rate was 12·1, as compared with 11·6 in the previous year, and the increase was almost entirely due to the influenza epidemic at the beginning of the year, which caused an increased mortality at the higher ages. Fatal street accidents caused 669 deaths as compared with 656 in the previous year, but the deaths of children under 15 were 14 less. The weather favoured infant life, and a decreased mortality from diarrhœa produced an infant mortality-rate of 59, the lowest ever recorded in London. The death-rate from phthisis was 0·91; from all forms of tuberculosis, 1·05; from cancer, 1·49; from pneumonia, 1·0; from bronchitis, 0·83; from pneumonia, bronchitis, and influenza combined, 2·23; and from diarrhœa and enteritis under two years, 7·6 per thousand births, to be compared with 12·0 in 1926.

The table for the metropolitan boroughs, excluding the City, shows that the lowest infant mortality-rates were recorded in Holborn (38), in Woolwich (42), and in

Lewisham (46); while the highest were in Paddington (79), Chelsea (76), and Shoreditch (74). From phthisis, the lowest rates were in Hampstead (0·44), in Kensington (0·65), and in Paddington (0·67); the highest were in Finsbury (1.36), in Bermondsey (1·22), and in Holborn (1·21). The lowest rates from pneumonia were recorded in Woolwich (0·67), Wandsworth (0·67), Hampstead (0·70), Greenwich (0·73), and Battersea (0·73); while the lowest rates from bronchitis were in Chelsea (0·50), Hampstead (0·59), Stoke Newington 0·59), and Hackney (0·60). The lowest rates from cancer were in Holborn (1·18), Shoreditch (1·27), and Bethnal Green (1·29); while the highest were in Chelsea (2·21), Hampstead (1·86), and Kensington (1·84). The puerperal fever incidence per thousand births was 3·57 for London and varied much among the boroughs, being lowest in Deptford (0·53), Kensington (1·13), and Stoke Newington (1·37); and highest in Chelsea (8·2), Fulham (6·98), and St. Pancras (6·68).

Dr. Menzies points out that the mortality from puerperal fever is much lower in boroughs with poorer-class populations, than in those populated largely by the well-to-do. Thus in the years 1921–25 the rate in the aggregate population of Bermondsey, Bethnal Green, Finsbury, Stepney, and Shoreditch was 0·88 per 1000 births, as compared with 1·80 in the aggregate population of Hampstead, Kensington, Lewisham, Stoke Newington, and Wandsworth. In 1927 the mortality from puerperal fever in London was 3·22 per thousand births among single women, as compared with 1·15 among married women, while the rates from other accidents of childbirth were 2·93 and 1·46 respectively. The suggestion is made that the statistics of maternal mortality from childbirth should be given for legitimate and illegitimate births separately.

Small-pox.

There were 5 cases of small-pox in the county. One case was of the mild type and imported from the north of England. The other 4 cases were apparently connected with an outbreak in Hendon which took place in March to May from some unrecognised source. This outbreak included 13 cases, of which 7 were fatal, including 2 of the 4 London cases. The first case of this outbreak was a man of 47, vaccinated only in infancy and his illness was considered to be chicken-pox. As the result of this failure in diagnosis, clothes were sent to the laundry and further cases occurred among the laundry workers, 4 of which proved fatal.

Anthrax.

During the first week of January 4 cases of anthrax occurred in connexion with the Zoological Gardens. All of the patients had been engaged in handling the carcasses of two elephants which had died from an illness the nature of which was not recognised until after the men were infected. Anti-anthrax serum was promptly administered and all the patients had fairly mild attacks. A prophylactic dose of serum was also given to 29 persons who had been in contact with the carcasses and no further cases occurred.

Encephalitis Lethargica.

There were 149 notifications of encephalitis lethargica, of which 114 were considered to be true cases. Of these, 49 had proved fatal up to March 31st, 1928.

A table indicates the present condition as regards 528 cases of encephalitis which came under observation from 1925 to 1927. Of these, 132 under the age of 16 and 111 over the age of 16 are stated to have recovered. Since November, 1925, the M.A.B. have provided 100 beds for children between the ages of 3 and 16 suffering from the after-effects of encephalitis. At Winchmore Hill Hospital Dr. G. A. Borthwick, the medical superintendent, has recently reported that this experimental unit has not been productive of curative results, but has proved valuable for observation purposes. It has also housed children whose mental condition unsuited them for outside life. In most cases he considers that the nerve-cells have been irretrievably damaged, but in a minority it may be possible by patient endeavour to educate other cells to function in the place of those destroyed. While he cannot recommend the Board to continue the section as an experimental unit with curative hopes, the need for housing these difficult and pitiful cases may be sufficient justification for carrying it on.

Cancer.

An analysis is given of the deaths from cancer in London during the period 1911 to 1920. The deaths are divided into three groups. In group 1, comprising growths of the upper alimentary tract, the death-rate per million among males was 336 as compared with 46 among females. In group 2, comprising growths of the reproductive system, the female death-rate was 509 and the male rate 52. In group 3, which includes all other cancers, the sex-incidence was approximately equal. The excessive female mortality in group 2 is shown to occur at an earlier age than the excessive male mortality in group 1. Some of the conclusions drawn from this analysis are: (1) that among persons over 35 the movements of the cancer mortality from 1850 onwards are correlated with the year of birth and not with progressive changes in conditions of life; (2) that if this same correlation holds in the future, the female mortality-rate will continue to decline while the male rate will increase further for some time; and (3) that a cancer diathesis may be the dominating factor and that the solution of the cancer problem may ultimately be found to depend upon the detection and modification of such diathesis.

Tuberculosis.

During 1927 2305 samples of milk from 32 counties were taken at London railway termini. The bacteriological examination was completed for 1969, of which 154, or 7·8 per cent., yielded tubercle bacilli, as against 4·5 per cent. in 1926. Information was sent to the county medical officers of health and as a result 59 cows were slaughtered under the Tuberculosis Order. In the case of 311 of the samples, the inoculated guinea-pigs died from an acute infection, and notice of this was also sent to the medical officers of health on the chance of its being due to unsatisfactory conditions in the cowsheds. The conditions of patients who received residential treatment under the council's tuberculosis scheme are investigated after the lapse of five years. Adult cases treated in 1921, numbering 3178, were investigated. Of 468 pulmonary cases without tubercle bacilli, 83·5 per cent. were alive; of 330 early cases with tubercle bacilli, 61·5 per cent. were alive; of 1299 moderately advanced, 34 per cent. were alive; of 858 advanced cases, 3·7 per cent. were alive; and of 223 "surgical" cases, 73·5 per cent. were alive. The particulars as to children under 16 were as follows: Of 271 pulmonary cases without tubercle bacilli, 90 per cent. were alive; of early cases with tubercle bacilli, 44·5 per cent. were alive; of 18 moderately advanced, 50 per cent.; and of 33 advanced 3 per cent. were alive. Of the 189 children treated for non-pulmonary tuberculosis, 153 were alive, of whom 71 were at school and 58 at work.

In 1926 arrangements were made to try artificial light treatment in connexion with the dispensaries. The number of cases treated has been small but the results have not been encouraging, and it is suggested that the best results will only be obtained in residential institutions. The scheme, however, is to be continued for another year. With the help of the Invalid Children Aid Association, 146 children living in contact with advanced consumptives were boarded out in the country. The arrangements for residential treatment for children have been improved and there is now no waiting-list either for pulmonary or surgical cases.

Venereal Diseases.

The new cases of syphilis were 357 and the new cases of gonorrhœa 813 in excess of the figures for 1926. Although a number of patients still fail to complete the full course of treatment, the ratio of attendances has gone up to 40 per new case. The number of non-venereal cases who present themselves for examination at the clinics has shown a steady increase. Thus in 1917 the non-venereal cases numbered about one-sixth of the venereal. In 1922 they numbered about one-third, and in 1927 they numbered more than one-half. The practitioners qualified for free supplies of salvarsan, &c., now number 446, as compared with 108 at the end of 1917.

SCHOOL MEDICAL SERVICE.

The school report indicates a steady progress of the improvement programmes dealing with the reduced size of classes, improved desks, and sanitary conditions. There is even a revolt against desks altogether. Infant departments are already equipped with table and chairs instead of desks.

Rheumatic Children.

Dr. J. Nairn Dobbie has continued his investigations with regard to rheumatic children. His material was 100 cases admitted under the council's scheme to Carshalton or Highwood hospitals. Of these children, 79 were below the average in nutrition; while 19 showed no evidence of heart affection, 42 were "suspicious," and 39 definitely affected. The tonsils were seldom markedly enlarged; adenoids were not a noteworthy feature, and the children did not belong to the "catarrhal," but rather to the nervous type. Their educational attainments were below the average. In 44 cases the parents stated that the children had been "nervous" all their lives, and Dr. Dobbie favours the view that this nervousness is inherited. In 66 there was history of rheumatic incidence on the "immediate" family, and in only 23 was there no rheumatic family history. The homes of 35 were slums and of 53 more semi-slums. Dr. Dobbie's impression was that the actual dampness in most of the houses was of small degree. In the case of such homes the washing of clothes is done at the public baths. To sum up the environment: "It would appear that no one disadvantageous factor stands out, but rather that each and all of the concomitants of poverty, poor houses, dampness, unhealthy sites, overcrowding, lack of ventilation and of sunlight, poor feeding, poor clothing, irregular habits, &c., destructively converge on these unfortunate children, who wilt along the lines their bias carries them, be it marasmus, rheumatism, tuberculosis, or the respiratory diseases generally."

Nursery Schools.

A special report deals with nursery schools in London, Manchester, and Bradford. At the outset it is pointed out that the medical objections to a large school—e.g., the McMillan with an average attendance of 220—have been overcome. These schools are needed *most* for the *most* neglected children from the worst homes. There should always be some bathing accommodation and *an open air régime*. The social function of the school is twofold; it trains the children and by *educating* the mothers, raises the home life to a higher level. "The potential under dog, rebel, or anarchist can be recognised among the entrants to the nursery school, but it is seldom they are not transformed into orderly, active, and happy citizens of their community." Educationally, no attempt is made to teach the three R's, and the most profitable pursuits are rhythmic movements, speech training, and hand work. Special training is needed for the staff and there is at present a dearth of such training centres. To be drawn to the work is not enough. "The nursery school teacher must not only be a lover of children, but a knower of children as well, and a knower of all the factors that make for health, growth, and happiness." The nursery school must develop its own methods and create its own traditions, and must not be absorbed into elementary education until it is strong enough to reform the infant school from the bottom. The education of the younger pupils has hitherto suffered too much from academic and bookish traditions proceeding from the top.

Dr. Menzies takes exception to the statement of the chief medical officer of the Board of Education that London is an area without an orthopædic scheme. He shows that the council has not neglected its duty to the crippled children of London despite the disadvantage that it is not the local authority under the Maternity and Child Welfare Act. He also gives reasons to show that the percentage of children who leave the physically defective schools of a district wearing apparatus is not a satisfactory index of the efficiency of the district's orthopædic scheme.

Mr. Sowden Hills, inspecting dental surgeon, has completed a comparison of English and Jewish children as regards dental condition. About 7000 children were examined. He finds that up to the twelfth year there is no marked divergence, but that after this age the English boys show an increase in the amount of dental decay while the Jewish boys show a decrease.

MENTAL HOSPITAL REPORTS.

THE *City of Leicester Mental Hospital* at West Humberstone had 941 patients on its books on March 31st, 1928. The ratio of mentally afflicted in Leicester is now 1 : 304; ten years ago it was 1 : 338. The recovery-rate for 1927 was 45·66 per cent. and the death-rate 6·31 per cent., figures which compare very favourably with the average for all public mental hospitals. Autopsies were held on 90 per cent. of those who died. Leave of absence was granted on 2870 occasions, and 52 per cent. of men and 37 per cent. of women patients have full or limited parole. Only 13 temporary and 3 permanent escapes resulted from this liberty. Small parties go out regularly for motor drives and to the cinema, and 78 per cent. of the patients are usefully employed. A cinematograph was installed in the recreation hall in the autumn. The old house of the medical superintendent has been converted into a female block; 32 new beds will be provided at the very low cost of £64 per bed. A new nurses' home is to be built. Two more members of the staff have obtained their M.P.A. certificate. A "Trinity" ultra-violet ray outfit has been installed in the X ray department. The pathologist reports on the malarial treatment of 12 more cases of general paralysis. Only one non-paralytic patient showed any improvement after induced malaria, but of 48 paralytics 25 per cent. have been discharged recovered and another 14·5 per cent. are "much improved." Reduction of the globulin and cell content of the cerebro-spinal fluid has been noticed, and in several cases the colloidal gold curve has changed to the luetic type. The investigation into the incidence of syphilis shows that of 218 males 7·5 per cent. and of 286 females 4·9 per cent. gave positive Wassermann reactions. The dental surgeon reports 347 operations, 99 inspections, and 27 refusals of treatment. All new admissions are inspected by him. The oral condition in general shows steady improvement.

The *City of Worcester Mental Hospital* at Powick housed 1056 patients at the end of last year. The discharge-rate was 43·52 per cent. and the death-rate 7·12 per cent. Post-mortem examinations were made in 65·75 per cent. of instances. The general health was good save for influenza and one case of erysipelas. Three babies were born in the hospital; two of the mothers have since been discharged. The new verandah for male patients fills a long-felt need, but the hospital still lacks clinical rooms, an admission block, and a convalescent villa. A continuous bath has been installed in one of the female wards. Thirty-three patients went out on trial, and 38 had parole within the estate. Six nurses obtained their M.P.A. certificate.

The *City of London Mental Hospital* at Stone, Dartford, had an active year in 1927. Of the 161 patients admitted 72 came on a voluntary basis. The recovery-rate was 30 per cent. for the certified and 40 per cent. for the voluntary patients. The death-rate was 5·86 per cent. There were 398 private and 246 rate-aided patients on the books at the end of the year. There was not a single case of infectious disease, and the general health was good. Parties of rate-aided patients were sent to the seaside. Tiresome patients are now segregated in Newstone House, and the female infirmary ward has been divided so that recent admissions can be treated apart from other inmates. The new single rooms are furnished like ordinary bedrooms, and every possible parole is allowed. Two new wireless sets and two more ultra-violet ray lamps have been installed. The farm continues to supply all the milk, mutton, pork, eggs, poultry, and vegetables required for the hospital. A small dairy has been built and equipped. A difficulty in obtaining female nurses has now been satisfactorily overcome, and one more attendant has obtained his M.P.A. certificate. Fourteen men and 11 women nurses are now registered or certificated. The consulting staff now comprises a physician, a surgeon, a gynæcologist, an ophthalmologist, and an aurist. The Minister of Health visited the hospital in the autumn.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JULY 28TH, 1928.

Notifications.—The following cases of infectious diseases were notified during the week:—Small-pox, 149 (last week, 173); scarlet fever, 1641; diphtheria, 926; enteric fever, 83; pneumonia, 654; puerperal fever, 54; puerperal pyrexia, 84; cerebro-spinal fever, 8; acute poliomyelitis, 8; acute polio-encephalitis, 2; encephalitis lethargica, 28; continued fever, 1; dysentery, 5; ophthalmia neonatorum, 118. No case of cholera, plague, or typhus fever was notified during the week.

The cases of small-pox were notified in the following 17 counties: London, 3; Derby, 17; Devon, 3 (Plymouth); Durham, 38; Huntingdon, 1; Lancaster, 1; Leicester, 2; Norfolk, 2; Northampton, 2; Northumberland, 7; Nottingham, 5; Stafford, 11; Yorks, East Riding 6, North Riding 2, West Riding 23; Glamorgan 10; Monmouth, 15; and 1 at the Port of Southampton.

The number of patients in the Infectious Hospitals of the Metropolitan Asylums Board on July 31st–August 1st was as follows:—Small-pox, 19 under treatment, 1 under observation; scarlet fever, 1743; diphtheria, 1791; enteric fever, 39; measles, 323; whooping-cough, 194; puerperal fever, 18 (plus 11 babies); encephalitis lethargica, 71; poliomyelitis, 2; "other diseases," 20. At St. Margaret's Hospital there were 20 babies (plus 15 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox or enteric fever, 19 (5) from measles, 2 (1) from scarlet fever, 32 (5) from whooping-cough, 22 (3) from diphtheria, 53 (11) from diarrhœa and enteritis under two years, and 25 (7) from influenza. The figures in parentheses are those for London itself.

Of the 14 fatal cases of measles outside London, 9 were reported from Liverpool and 3 from Birmingham. Of the 27 fatal cases of whooping-cough outside London, 8 were reported from Liverpool, 5 from Birmingham, and 4 from Newcastle-on-Tyne. The deaths from diarrhœa were about 50 per cent. more than in the previous week.

The number of stillbirths registered during the week was 276 in the great towns (corresponding to a rate of 39 per 1000 births) including 39 in London.

Paratyphoid in the London Area.—The figures given above record a large increase over the previous week in the notifications of "enteric fever" and in the number of admissions under this head to M.A.B. hospitals. Since the return was made up upwards of 100 cases of paratyphoid B. infection have been notified in the London area, the cases for the most part being of a mild type, although one fatal result has been reported. The wide distribution suggests the infection of some common article of food, cream being under suspicion rather than the milk or water supply. The most intense centres of infection have been in Epsom and Kensington, although Wandsworth, Fulham, and Westminster have borne their share. The outbreak has been somewhat confused in the popular mind with a group of cases of food poisoning of a very different type among police officers in the Westminster area with a fatal case of toxæmia, in which death was presumed to have resulted from eating infected ham; the pathological report from King's College Pathological Laboratory confirmed this finding, but the inquest has not yet been concluded.

Reviews and Notices of Books.

THE PRESCRIBING OF SPECTACLES.

Third edition. By ARCHIBALD STANLEY PERCIVAL, M.A., M.B., B.C. Cantab. Illustrated with diagrams. Bristol: John Wright and Sons, Ltd. 1928. Pp. 239. 15s.

THIS book, which is written by an acknowledged authority on mathematical optics and on the minutiæ of spectacle prescribing, has been rewritten and enlarged. It contains much interesting matter besides the usual accounts of the optics of refraction and of the methods of testing the refraction of the eye. For retinoscopy the concave mirror is recommended on the ground that illumination is better than with the plane mirror; the author admits, however, that preference for one or the other form is to a great extent a matter of habit. The refraction of the macula can only be accurately determined in most cases with a dilated pupil, and this is specially important in myopia where the disc is liable to be tilted and the fundus stretched. For the accurate estimation of the angle of astigmatism the use of cylinders in retinoscopy is far preferable to the refraction of the two meridia by spherical lenses alone. Here the author mentions a point which is not generally known. When the correct cylinder in the trial frame is at the wrong angle the error, shown by the direction in which the shadow moves, is greatly exaggerated. This enables the surgeon to judge how to shift the axis of the cylinder until an equal shadow in all meridia is obtained. The ophthalmometer is not recommended for accurate work, since it only gives the astigmatism of the anterior corneal surface. Dr. Percival points out that tilting the lens downwards increases the spherical and still more the cylindrical power. This device may be of practical value in some cases of high myopia with astigmatism; also in prescribing temporary glasses after a cataract operation, the immediate effect of which is to cause some astigmatism with the axis horizontal. On the subject of periscopic spectacles Dr. Percival notes that the anterior convexity of a high plus lens is often too high. For instance, if a lens of +10D is to be made periscopically on a base of −7D, the anterior convexity should not be +17D but +16 D, owing to the distance from the eye. These and other details are worked out mathematically and the exact figures are given in tables. More than a third of the book is devoted to the application of mathematical optics to various practical problems in the prescribing and fitting of glasses.

FRACTURE OF THE PELVIS.

Beiträge zur Kenntnis der Beckenbrüche und Beckenluxationen. By ANDERS WESTERBORN. Upsala and Stockholm. 1928. Pp. 375.

THIS monograph is Supplement VIII. of Vol. LXIII. of the Acta Chirurgica Scandinavica and comes from the surgical clinic of the University of Upsala under the authority of Prof. Gunnar Nyström. The author wrote it in Swedish, and it has been translated into German by Dr. H. Flex. Dr. Westerborn, in his preface, states that since the introduction of X rays no thorough study of the subject has appeared and that a clinical rontgenological investigation of the material is required not only as regards the industrial efficiency of the surviving patients, but also as to their anatomical recovery and subjective symptoms. The author gives statistics of the causes of fracture in 278 cases as far as ascertainable; 143 of these were falls from a height (including eight cases of suicide by jumping out of window), 84 were caused by crushes, and the exact mechanism of injury was unknown in 34 cases, although mechanically propelled vehicles were concerned in most of them. Under the heading of "Fracture of the Pelvis" are included injuries ranging from slight to severe, some so severe that recovery is only just possible. Therefore any statistics as to prognosis are valueless unless they are classified. The gravity of a case depends largely upon the presence or absence of injury to important structures inside the pelvic cavity. Chief among these are rupture of the bladder and urethra (20 per cent. of cases). Injury to the kidneys, although included in these statistics, hardly seems attributable to pelvic fracture. Of 15 cases of rupture of the bladder eight recovered. Early operation and perineal drainage in this injury as well as in ruptured urethra is of the greatest importance as a preventive of sepsis, which is the most frequent cause of death, apart from concomitant injuries. Diagnosis of bladder rupture by the injection of sterile air and subsequent X ray photograph is strongly recommended. A tied-in catheter does not prevent the occurrence of sepsis and seems to increase the liability to stricture in cases of ruptured urethra.

The general mortality amounted to 12 per cent. of all the cases here recorded. Double vertical fracture of the pelvic ring was the most fatal (30 per cent.), while fracture of the expanded portion of the ilium was least deadly, having a mortality of only 3 per cent. 114 pages of the work are taken up by small print records of case-histories, illustrated with outlines of X ray pictures. There is a copious bibliography and 16 plates of excellent reduced reproductions of X ray photographs. There is, unfortunately, no index.

This is a very painstaking and conscientious study of the subject.

SYPHILIS.

Second edition. By HENRY H. HAZEN, A.M., M.D., Professor of Dermatology and Syphilology, Georgetown University and Howard University. London: Henry Kimpton. 1928. Pp. 643. 42*s*.

THE progress in syphilology since the first edition of this work appeared in 1919 has necessitated a thorough revision, which has been achieved with practically no alteration in size. The earlier chapters contain useful statistics of syphilis in various sections of the American population, as well as a valuable discussion on infection and immunity. Excellent accounts are given of the early stages of the disease. The cutaneous manifestations, which are classified according to the system of the American Dermatological Association, are particularly well described and illustrated; a valuable feature is the note of the histological changes in each type of lesion. The late lesions are dealt with systematically. The chapters on the vascular system and the genito-urinary tract are of a high standard and excellent coloured plates of the cystoscopic appearance of vesical lesions are included. Not many surgeons will support the author's opinion that syphilitic bone disease is a very frequent cause of spontaneous fractures, nor that the clavicle is the favourite bone for syphilitic involvement; this last statement is, moreover, at variance with the statistics given in the earlier part of this chapter. Radiographic evidence of a syphilitic lesion has frequently been noted in Charcot's joints; Dr. Hazen believes that most manifestations of this condition, *especially* those of the hypertrophic type, are due to the direct action of the spirochæte rather than of neuropathic origin. He devotes considerable space to involvement of the central nervous system, drawing special attention to the high proportion of cases of early syphilis in which this system is affected, and to the necessity of examination of the cerebro-spinal fluid. The various types of neurosyphilis in all stages are lucidly described and full details are given of the technique and value of the Lange gold chloride test. Tryparsamide does not meet with his unequivocal approval, but Dr. Hazen is very favourably impressed by the results of intraspinal treatment after the technique of Swift and Ellis, which is fully discussed. The treatment of general paralysis by malarial therapy is *dismissed* in a very cursory manner.

Readers who appreciate the full details of treatment for the various stages of the disease given in most modern works of British origin will be disappointed with the chapter on treatment. The sections on the antenatal treatment of infected women, and the treatment of congenital syphilis in infants are certainly not full enough. As to the general principles of treatment, there are evidently differences in practice between England and America. The therapeutic value of bismuth appears to us to be underrated in this book, the author's experience of a high percentage of albuminuria following the administration of this remedy being unusual. Of the organic arsenical compounds, arsphenamine is recommended as giving good results in *routine practice*; toxic effects with both neo-arsphenamine and sulfarsphenamine appear to be more frequent than with similar preparations of European origin. The simultaneous administration of arsenical compounds and metallic remedies is not recommended.

Throughout the book Dr. Hazen quotes freely from authoritative sources, and gives extensive lists of references at the end of each chapter; he would have done well also to make clear his own opinion, based on personal experience, especially where controversial questions are involved. Students and practitioners will miss this guidance, but will appreciate the impartiality which characterises what is on the whole an excellent work.

DEAFNESS AND ITS ALLEVIATION.

By VINCENT NESFIELD, F.R.C.S., Major I.M.S. (ret.); Ophthalmic Surgeon, Queen's Hospital for Children. London: H. K. Lewis and Co., Ltd. 1928. Pp. 85. 7*s*. 6*d*.

UNDER this title Mr. Nesfield sets out to describe an operation he has designed for the relief of deafness. This consists in gouging away the bone to make a channel 14 mm. in diameter parallel to, and behind, the external auditory canal. The aim in view is to produce an aperture into the middle ear about 5 mm. in diameter. According to the author's description, this "boring" leads into the attic of the middle ear; the mastoid antrum is usually "non-existent, or only present as a thin red line of mucous membrane." The bridge between the "boring" and the external auditory canal is cut away to a depth of about 10 mm., and the external meatus split to make a flap, which is stitched to the under surface of the skin incision. Two tubes, 5 mm. in diameter, are inserted from the meatus backwards into the canal made in the mastoid; these are removed on the next day, and firm plugging inserted and renewed daily for three weeks with the object of keeping the opening patent. Nevertheless, the skin opening nearly always closes over at the back of the external auditory meatus; in time a very thin membrane forms *in this* situation. Mr. Nesfield claims that the operation improves the hearing in six different ways: (1) by rendering the Eustachian tube patent; (2) by allowing air to enter the middle ear directly through the *new* opening, "and this appears to be the most potent factor"; (3) sound waves impinge on the membrane which forms over the new opening; (4) the *channel* not only aerates the middle ear but drains it of mucus; (5) the boring and the increased vascularity resulting in the healing process produce a reflex effect on the cochlea; and (6) the increase of the total space of the middle ear increases the resonance. As to (1) he does not attempt to explain how or why this effect is attained. The benefit claimed in (2) cannot occur when the opening closes over as, on his own showing, it nearly always does; this criticism applies also to (4), while (5) is a highly speculative statement.

The book appeals rather to the general public than to the medical profession; thus, of its 85 pages, but 14 are devoted to a description of the operation, its after-treatment, and its results, while the previous 56 pages contain a popular account of the anatomy and physiology of the ear, and of "the nature of deafness." The author says that, as it is not possible to gauge the result under three years, it is difficult to show exact results. It may be difficult, but it is surely not impossible, to show the approximate results on all patients operated on three years and more ago. Such tables of the results of treatment have been compiled by other authors of novel methods, and the profession has a right to expect some attempt to show the result in all cases treated by one who makes large claims to alleviate such a disease as chronic deafness.

ACCIDENTS, AND PROBLEMS ARISING THEREFROM.

Lehrbuch der Unfallheilkunde. By Dr. PAUL JOTTKOWITZ, Oberregierangsmedizinabrat, Chief of the Orthopædic Installation, Berlin. Munich: J. F. Lehmann. 1928. Pp. 280 M.15.

THAT this book must cover a great deal of ground is evident when we reflect on the immense variety of injuries that result from accidents. No work quite like it has appeared in this country, where information has to be collected laboriously from text-books on medicine, surgery, orthopædics, and jurisprudence. In Germany, the pioneer country of workmen's insurance, quite a literature has grown up of which this volume is representative. The treatment of injuries is not considered in detail, but their disabling effects are discussed fully, and also the difficult subject of the estimation of wage-earning capacity after crippling injuries or loss of parts. In this last connexion, amputation sites and artificial limbs come under review. The extent of the field will be indicated by the quotation of some of the headings, which range from accident insurance, infected wounds, animal infections such as glanders, tuberculosis, diabetes, acromegaly, and arthritis, to artificial limbs. This work is in some sort an epitome of medicine and surgery from an industrial insurance point of view, the diseases of the special senses being excluded. It is of considerable medico-legal value, and certainly should be studied by medical officers concerned with the relations between patients and employers.

DISEASES OF THE BLOOD AND BLOOD-BUILDING ORGANS.

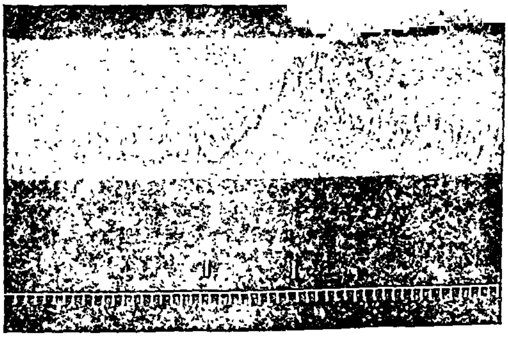
Clinical Pediatrics. Vol. XI. By WILLIAM PALMER LUCAS, M.D., Professor of Pediatrics and ALFRED H. WASHBURN, M.D., Instructor in Pediatrics, University of California Medical School. Supervising Editor, ROYAL STORRS HAYNES, M.D., Clinical Professor of Diseases of Children, College of Physicians amd Surgeons, New York. London and New York: D. Appleton and Co., Ltd. 1928. Pp. 233. 16*s*.

DISEASES *of the blood and blood-forming system* form a small but important division of the ills of children. In this substantial volume there is no padding, and an admirable feature is the inclusion of illustrative cases. These are all well chosen and are worthy of close study by those concerned with the diseases of children and adults alike. The peculiarities of the blood picture in children, both in health and disease, are well described; the sections on the diagnosis and treatment of the various conditions are satisfactory, but the pathological side might well have been further elaborated.

New Inventions.

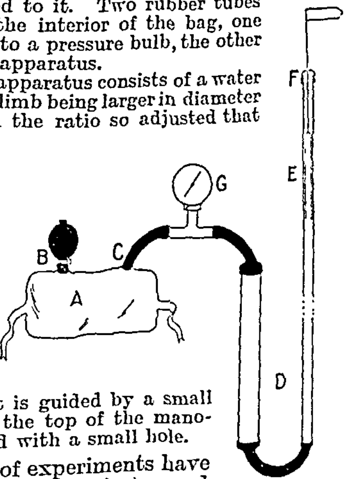
APPARATUS FOR RECORDING HUMAN BLOOD PRESSURE.

HITHERTO it has been impossible to obtain continuous records of human blood pressure with simple apparatus. Erlanger[1] obtained short continuous records at intervals, but the only apparatus devised for taking continuous records is a complicated apparatus employing an electric valve invented by Kolls in 1920.[2] Moreover, this apparatus did not record rapid variations in blood pressure. Consequently, much important work in relation to variations in blood pressure in human subjects under different conditions either has had to be omitted or has been performed by difficult and unreliable means. The simple apparatus about to be described is a step towards remedying this lack. As will be seen, it is a combination of some well-known apparatus slightly modified, and the instrument is obviously an object for improvement. It consists of two sections.



Continuous human blood-pressure record, showing the effect of respiratory cessation in the inspiratory position. Time intervals 5 secs.

1. An armlet made of a collapsible rubber bag (A), the outer surface of one side being made rigid by means of stiff canvas attached to it. Two rubber tubes communicate with the interior of the bag, one (B) being connected to a pressure bulb, the other (C) to the recording apparatus.
2. The recording apparatus consists of a water manometer (D), one limb being larger in diameter than the other, and the ratio so adjusted that one millimetre of mercury difference in actual blood pressure moves the liquid in the recording limb of the manometer an equal distance. To record on smoked paper, a special glass float (E), carrying a light celluloid pointer, is used. The stem of the float is guided by a small glass cap (F) fitting the top of the manometer and perforated with a small hole.



A large number of experiments have been done on human subjects, and the best procedure has been found to be as follows. The armlet is arranged immediately above the elbow, and the subject sits or lies with the arm supported in a comfortable position. The pressure in the bag is raised to 20–25 mm. Hg below the subject's systolic pressure. The requisite tension in the bag to produce this pressure can be ascertained by inserting a small meter (G) in a by-tube. In this way, 10-minute continuous records can be obtained without the subject experiencing any discomfort. It should be pointed out that the apparatus does not record systolic blood pressure but variations in blood pressure. By employing a simple factor the actual blood pressure can easily be ascertained if desired. The tension in the bag is, of course, considerably above the venous blood pressure and, consequently, volume effects are excluded. A typical tracing obtained with this apparatus is shown.

J. H. THOMPSON, B.Sc.,
Demonstrator in Physiology, Department of Physiology, Middlesex Hospital Medical School, W.

THE LANCET.

LONDON: SATURDAY, AUGUST 11, 1928.

HE INTERNATIONAL UNIT OF X RAYS.

AT the First International Congress of Radiology, ld in London three years ago, there was a discussion the necessity of establishing an international unit be used as the basis of all X ray measurement of sage. It was felt at the time that satisfactory ogress in treatment with X rays would not be ssible without a unit which could be universally lopted. It was therefore resolved that an Inter- tional X Ray Unit Committee be formed, and the ritish X Ray Unit Committee, which was established 1923, was requested to communicate with the ysical and radiological societies of the principal untries throughout the world with a view to the mination of representatives to constitute such an ternational committee. During the last three years e British X Ray Unit Committee has had the matter hand and a committee consisting of two representa- es from each of 19 different countries has been rmed. Each country was invited to submit the mes of two representatives—one a medical man d one a physicist—to serve on this committee. preserve a balance, the British Empire was repre- ted by two members only.

The representatives were invited to submit their ws on the X ray unit and the measurement of sage, and it was at once evident from the replies eived that the subject was one in which great erest was taken. A summary of the various points sed was prepared and submitted as a basis for cussion at a meeting of the International X Ray it Committee which met during the Second Inter- tional Congress of Radiology held last week at ckholm. Representatives from the following ntries were present at the meeting: Belgium, cho-Slovakia, Denmark, Great Britain, France, rmany, Italy, Japan, Norway, the United States America, Russia, Spain, Sweden, and Switzerland. is gratifying to know that unanimous agreement arrived at in the committee meeting concerning main points under discussion. The following mmendations put forward by the International mittee were unanimously adopted at a general eting of the Congress:—

. That an international unit of X radiation be pted.

. That this international unit be the quantity of radiation which, when the secondary electrons are y utilised and the wall effect of the chamber is ided, produces in 1 c.cm. of atmospheric air 0° C. and 76 cm. Hg pressure such a degree of ductivity that one electrostatic unit of charge measured at saturation current.

. That the international unit of X radiation be led the "Rontgen," and that it be designated by letter R.

. That various standard methods be employed to ablish the unit.

. That for all comparative purposes it is advisable employ ionisation chambers which have been ibrated in terms of a standard chamber for radiation of the various qualities employed. It is advisable to make the wall effect of these chambers mall as possible.

6. That the practical instrument used to measure X ray output be called a dosage meter.

7. That the constancy of the indications of the dosage meter be tested by means of gamma radiation emitted from a definite quantity of radium element, the measurement being carried out always under the same conditions.

8. That any specification of dosage is incomplete without specifying the quality as well as the quantity of the radiation. The quality of X radiation used for practical purposes is very varied and it would be impracticable to give a complete specification of it; but much information can be obtained from a knowledge of the degree of absorption of the radiation in standard materials, the peak voltage applied to the tube together with the filter employed, and the general character of the high tension apparatus. For practical purposes the quality may be expressed by stating the half value layer in a suitable material or by stating the effective wave-length as determined by the percentage amount of radiation transmitted through a given thickness of a suitable material (copper or aluminium).

In view of the fact that rapid progress is being made in methods of X ray measurement and in our knowledge of X ray phenomena, the Committee felt that the above recommendations should be regarded as provisional. They may be modified later in the light of further information. The adoption of the resolutions marks an important step in the measurement of X ray dosage. Not only will the confusion which has hitherto existed in radiology by the employment of the letter R to denote entirely different quantities be removed, but it will now be possible for a radiologist in one country to reproduce accurately an X ray dose and thus be enabled to compare his results with those of radiologists in other countries. Hitherto this has been impossible since there has been no international agreement concerning the unit in terms of which the dose should be measured. Emphasis has been laid on the need for specifying the quality as well as the quantity of radiation employed in treatment. The recommendations indicate how the quality may be specified, and it would be well in order to obtain as close agreement as possible if radiologists were to employ the methods suggested. The correlation of the physical dose and the biological dose needs careful consideration by the International Committee as it presents many difficulties. Whether these difficulties can be surmounted and a correlation be found is still an open question.

The International X Ray Unit Committee has been authorised to continue its deliberations and to submit a further report for consideration at the next Congress to be held in Paris in 1931. Prof. K. M. G. SIEGBAHN (Upsala) was elected chairman, and Prof. E. A. OWEN (Bangor) and Prof. HERMANN HOLTHUSEN (Hamburg) honorary joint secretaries of the International Committee during the ensuing three years. The British X Ray Unit Committee, which has had the financial support of the Medical Research Council, is to be heartily congratulated on the excellent work it has done during the last three years in preparing the way for the adoption of the resolutions by the Second International Congress of Radiology.

◆

DISSOCIATED JAUNDICE.

SINCE the observations of certain French biochemists called attention to the fact that the elimination of bile-salts and of bile-pigments do not necessarily run a parallel course in certain cases of icterus, the study of so-called dissociated jaundice has been actively pursued by many observers. A recent article by CHABROL, BÉNARD, and BARIÉTY[1] gives an account of the researches carried out by them during the last nine years on the excretion of bile-salts. The detection of bile-salts is fairly easy, but the quantitative estimation of these bodies either in urine, blood serum, or even in bile itself is a matter of great difficulty. Thus in blood serum these authors have found it impossible to obtain an estimate of the amount of bile-salts present by any method depending on diminution of surface tension. They have, however, been able to apply a modification of Pettenkofer's reaction which will give a positive result in dilutions as great as 1 in 10,000. In the case of urine, Pettenkofer's reaction has also been employed, but here surface-tension estimations have proved of value when carried out by a special technique. It has been found that the NaCl-content of the fluid is of importance, since the concentration of this salt may produce considerable modifications in the results obtained. When duodenal secretions, recovered by means of a duodenal tube, are examined, the estimation of the bile-salts is a simple matter as these bodies are always present in considerable concentration. The French observers have found that methods of estimating surface tension are the most readily applicable in this medium and give results of great utility, even if no claim to fine exactitude can be made. The principal conclusions drawn from their observations are as follows:—

(1) In normal circumstances, bile-salts can never be found except in the first part of the small intestine, the duodenal fluid giving figures in the neighbourhood of 15 g. per litre. The authors have given the name of biliary index to the ratio salts/pigments, and find that this index is normally in the region of 40. In the blood serum they are able to assert that if bile-salts are ever present in physiological conditions their concentration is certainly below 0·1 g. per litre, and as regards the urine they are again unable to find any evidence of the presence of these bodies normally.

(2) In the case of hæmolytic jaundice, the findings are comparable to those in the normal—i.e., bile-salts cannot be found in the blood serum and they do not lower the surface tension of urine. Duodenal tubage, on the other hand, gives a ready demonstration of the dissociation which is held to be present in jaundice due to excessive hæmolysis, the biliary index in such cases being as low as 6 instead of the normal 40.

(3) In obstructive jaundice bile-salts should theoretically be found with the greatest facility. Some 10–15 g. of bile-salts are normally excreted daily in the bile, and in cases of grave obstruction to the biliary passage it would be expected that a large part of this would appear in the urine, but such does not appear to be the case. In a series of 15 cases of grave obstructive jaundice, the authors have been surprised to find in the blood serum only the smallest trace of the bile-salts in spite of the presence of a high concentration of bile-pigments in the blood. In reality, the proportion of bile-salts was ten times less than that of pigments, whereas in normal bile these proportions are reversed. The first possible explanation of this fact is that the renal threshold for bile-salts is much lower than that for bilirubin. The study of the urine in such cases does not support this thesis, for whenever the concentration of bile-salts in the urine is measured, it is found that the amount eliminated in obstructive jaundice is relatively small, and there have often been cases of obstructive jaundice in which the pigmentation was of the deepest degree, and yet the urine showed an almost complete absence of bile-salts.

The conclusion is drawn that any icterus which goes on for a long time tends to be accompanied with a disassociation of the amount of bile constituents excreted, the pigments being the elements showing extreme retention. According to the theory of
LEMIERRE and BRULÉ, such a condition, in wh
Hayes's reaction is negative, in spite of an inte
choluria, indicates dysfunction of the hepatic cells,
following CHABROL, BÉNARD, and BARIÉTY, the
explanation would appear to be that there is a gen
deficiency of bile-salts in the organism in these ca
and they base this belief on the fact that the small qu
tities of bile which can be recovered by duodenal tub
in such circumstances demonstrate a consider
diminution in the relative content of bile-salts.
explain such a disappearance of bile-salts from
bile itself they have recourse to the fact that ch
sterol is noticeably increased in the blood in all th
circumstances, and they hold that it is possible
this increase of blood cholesterol is in part due
failure of the liver to form bile-salts. Apart from
the fact that the normal circulation of bile-salts f
the liver to the intestine and then back by the po
vein to the liver has been interrupted by the pres
of an obstruction, is thought to be sufficient to b
about a steady diminution in the bodily reserve
bile-salts.

In conclusion, these authors have attempted
discover whether there are not frequently variation
the excretion of bile-salts amongst patients suffe
from diseases unaccompanied by jaundice. Here, ag
caution must be observed because the surface ten
of urine can be materially affected by many bo
in addition to bile-salts—chlorides, albumin,
polypeptides being outstanding examples. In m
cases of secondary carcinoma of the liver, and du
the course of certain acute infections, observation
the surface tension, together with a modified Pet
kofer's reaction, point to the possibility of an exces
excretion of bile-salts. These findings must, howe
be accepted with reserve. Still more interesting
certain observations on the effect of injecting an ex
of bile-salts into the blood, it being found that
intravenous injection a concentration much hig
than that ever observed during biliary obstruc
can be produced without any accompanying pru
or bradycardia.

ACTIONS AGAINST GOVERNMENT DEPARTMENTS.

GOVERNMENT departments are far from enjoyin
good press at the moment. Judges abuse them
well-reported phrases; Prof. J. H. MORGAN has b
attacking them in two articles in a popular even
newspaper; the Lord Chief Justice is understood
be devoting the Long Vacation to preparing
publication a book in criticism of bureaucra
Though it is not unknown at public dinners for
civil service to hear itself praised for its compete
integrity, and self-effacement, there are plenty
cases (especially during war time) where Governm
departments have deserved the condemnation t
have received. In one sense bureaucracy is increas
and must increase. The manifold activities of
Home Office and the Ministry of Health—in s
directions as the inspection of factories, the notifi
tion of diseases, and the general supervision of hea
services—are in a measure an infringement of perso
liberty. But it is too late to say that Governm
departments are not to interfere in these matt
On the other hand, the departmental attitude
easily exceed what is reasonable, especially in
absence of legal check. The medical profession m
not be specially concerned, but it remembers
difficulties when panel doctors found the Minister
Health exercising not only executive but also judic

functions and seeking to bar the avenue of appeal to the law courts. As a member of the public, too, the practitioner may be surprised at the results of the doctrine that the King can do no wrong. A doctor's motor-car may be smashed by a negligently driven Army lorry and the only remedy may be a futile claim against the corporal at the steering-wheel. Or, if a postman steals a registered and insured postal packet, it may turn out that the compensation is merely discretionary not contractual. It is not unimportant, therefore, to inquire the nature of the legal liability of State departments and to consider possible reforms.

Mr. J. W. GORDON, K.C., has recently published a pamphlet on "The Crown and the Courts" (Stevens, 1*s.*), setting out the case for reform illustrated by instances and judicial comments. His examples of the sins of Government departments are set out under several heads such as "usurpation of authority," "trespass to property," "imposition of unauthorised taxation," and "delay or denial of justice"—a damning list which suggests that the time has come for a fresh Magna Charta. The difficulty is at present that the Crown is immune from liability for the wrongful acts of its servants. Petition of Right will not lie for what the lawyers call a tort. There is some doubt whether this rule is historically well founded, but it is solidly established to-day and nothing but a new statute could upset it. In at least one of our self-governing Dominions the rule does not exist. Under an Act of 1903 the Commonwealth of Australia can be made responsible for the actions of its officers just as a master can be made liable for the actions of his servants. Australia has abolished the complicated and anachronistic procedure by way of Petition of Right and has put the subject when suing the Crown in no worse position than if he were suing another subject. Something of the kind is required in England. The obsolete procedure and the one-sided prerogative ought to be modernised and modified. After the war a strong committee was appointed by Lord BIRKENHEAD, when Lord Chancellor, to consider the position of the Crown as litigant and to prepare a Bill to amend the law as found desirable. After long delay, as Mr. GORDON says, a Bill was produced more than a year ago but nothing more has been heard of it. It may be urged that the matter is complicated and not free from controversy. The departments naturally fear a multitude of petty claims—for example, if the Admiralty carries out big gun firing near the coast and windows are broken. Nevertheless, it is understood that most of the Government departments are prepared to accept the Bill. Little will be done unless public opinion applies pressure. Mr. GORDON'S pamphlet is therefore timely, and those who wish to pursue the matter beyond the mere collecting of anthologies of judicial abuse of Government departments should study the draft Bill which was published as Cmd. 2842 in April, 1927.

AN International Conference on Light will be held at Lausanne and Leysin from Sept. 10th to 13th next. Those taking part will include Prof. H. C. Dorno (Davos), Prof. C. Fabry (Paris), Prof. V. Henri and Prof. Bloch (Zurich), Dr. Leonard Hill (London), Prof. Hausmann (Vienna), Dr. Alfred Hess (New York), Prof. Axel Reyn (Copenhagen), and Dr. A. Rollier (Leysin). Among the subjects to be discussed are the methods of measuring the energy and biological activity of light rays, irradiated foods and sterols, the climatic and light therapy of various forms of tuberculosis. Dr. G. Murray Levick is acting as general honorary secretary of the Conference in England, but all entrance fees and general inquiries should be addessed to the Secrétariat-général de la Première Conférence Internationale de la Lumière, Lausanne, Switzerland.

Annotations.

"Ne quid nimis."

THE DIAGNOSIS OF TUBERCLE IN GENERAL PRACTICE.

THE diagnosis of consumption presented no difficulty to the practitioner of 50 years ago. If cough, blood-spitting, wasting, night-sweats, and hectic flush proclaimed the disease the patient's friends were advised that he was in a state of consumptive decline, and the verdict was received as a sentence of death. The customary precautions were taken to postpone, as far as might be, the inevitable end. The dangers of fresh air were met by closed windows whose crevices were further sealed by crimson covered bolsters filled with sand. The bed was screened by heavy curtains, scarcely withdrawn to permit access to the sufferer. The patient's resistance was supported by drugs liberally prescribed, and blood-letting was resorted to in extremity. When the end came, both doctor and relatives had the satisfaction of knowing that everything possible had been done, and bowed themselves before the mysterious dispensations of Providence.

We know to-day that the symptoms and signs on which the doctors of a previous generation relied for diagnosis represent the last stages of disease and indicate as certainly as in the days of the younger Dumas the near approach of death. The importance of diagnosis at a much earlier stage as offering the only hope of cure has been emphasised by every teacher since the day when Koch made his great discovery. Indeed an almost morbid care has been exercised in the attempt to discover the earliest possible signs of tuberculosis. Great importance has been attached to almost imperceptible variations in breath sounds, and the skill of a piano-tuner demanded to determine relative changes in the percussion note of the lung apices. In recent years thousands of persons have been stigmatised as tuberculous and admitted to sanatoriums, where they have received treatment for non-existent disease, and been saved from a peril that never threatened. A more rational appreciation of the nature of tuberculosis, and in particular of the distinction between infection and disease, has led to a more reasonable attitude on the part of those specially interested in the care of the tuberculous. But the general practitioner, mindful of the teachings of his student days, and aware of some change in the modern attitude, remains in doubt as to the course he should pursue when confronted by a doubtful case. Any lack of acuity on his part may deprive his patient of the only chance of cure, while over-scrupulous care may awake groundless fears and pave the way to chronic invalidity. A false step on his part may not only involve a period of needless inactivity for his patient, it may be responsible for either of those twin obsessions, the dread of the phthisophobic or the craving of the phthisophilic. The latter condition is perhaps more common than the former.

Dr. Lawrason Brown, of Saranac Lake, has endeavoured[1] to clear the air by setting up a diagnostic standard representing the minimal requirements for diagnosis. If he has erred it is on the side of boldness, but he has undoubtedly turned the hose of common sense on the sacrificial fires of the phthisical expert, and the practitioner whose hand may have lost some of its cunning and whose ears are slightly dulled by the passage of time will be grateful to him. His diagnostic criteria are: (1) hæmoptysis of a drachm or more; (2) pleurisy with effusion; (3) moderately coarse râles above the third rib and the third vertebral spine; (4) a parenchymatous Rontgen ray lesion in the same area; and (5) tubercle bacilli in the

Bénard, and Bariéty[1] gives an account of the researches carried out by them during the last nine years on the excretion of bile-salts. The detection of bile-salts is fairly easy, but the quantitative estimation of these bodies either in urine, blood serum, or even in bile itself is a matter of great difficulty. Thus in blood serum these authors have found it impossible to obtain an estimate of the amount of bile-salts present by any method depending on diminution of surface tension. They have, however, been able to apply a modification of Pettenkofer's reaction which will give a positive result in dilutions as great as 1 in 10,000. In the case of urine, Pettenkofer's reaction has also been employed, but here surface-tension estimations have proved of value when carried out by a special technique. It has been found that the NaCl-content of the fluid is of importance, since the concentration of this salt may produce considerable modifications in the results obtained. When duodenal secretions, recovered by means of a duodenal tube, are examined, the estimation of the bile-salts is a simple matter as these bodies are always present in considerable concentration. The French observers have found that methods of estimating surface tension are the most readily applicable in this medium and give results of great utility, even if no claim to fine exactitude can be made. The principal conclusions drawn from their observations are as follows:—

(1) In normal circumstances, bile-salts can never be found except in the first part of the small intestine, the duodenal fluid giving figures in the neighbourhood of 15 g. per litre. The authors have given the name of biliary index to the ratio salts/pigments, and find that this index is normally in the region of 40. In the blood serum they are able to assert that if bile-salts are ever present in physiological conditions their concentration is certainly below 0·1 g. per litre, and as regards the urine they are again unable to find any evidence of the presence of these bodies normally.

(2) In the case of hæmolytic jaundice, the findings are comparable to those in the normal—i.e., bile-salts cannot be found in the blood serum and they do not lower the surface tension of urine. Duodenal tubage, on the other hand, gives a ready demonstration of the dissociation which is held to be present in jaundice due to excessive hæmolysis, the biliary index in such cases being as low as 6 instead of the normal 40.

(3) In obstructive jaundice bile-salts should theoretically be found with the greatest facility. Some 10–15 g. of bile-salts are normally excreted daily in the bile, and in cases of grave obstruction to the biliary passage it would be expected that a large part of this would appear in the urine, but such does not appear to be the case. In a series of 15 cases of grave obstructive jaundice, the authors have been surprised to find in the blood serum only the smallest trace of the bile-salts in spite of the presence of a high concentration of bile-pigments in the blood. In reality, the proportion of bile-salts was ten times less than that of pigments, whereas in normal bile these proportions are reversed. The first possible explanation of this fact is that the renal threshold for bile-salts is much lower than that for bilirubin. The study of the urine in such cases does not support this thesis, for whenever the concentration of bile-salts in the urine is measured, it is found that the amount eliminated in obstructive jaundice is relatively small, and there have often been cases of obstructive jaundice in which the pigmentation was of the deepest degree, and yet the urine showed an almost complete absence of bile-salts.

The conclusion is drawn that any icterus which goes on for a long time tends to be accompanied with a disassociation of the amount of bile constituents excreted, the pigments being the elements showing extreme retention. According to the theory of Lemierre and Brulé, such a condition, in which Hayes's reaction is negative, in spite of an intense choluria, indicates dysfunction of the hepatic cells, but following Chabrol, Bénard, and Bariéty, the true explanation would appear to be that there is a general deficiency of bile-salts in the organism in these cases, and they base this belief on the fact that the small quantities of bile which can be recovered by duodenal tubage in such circumstances demonstrate a considerable diminution in the relative content of bile-salts. To explain such a disappearance of bile-salts from the bile itself they have recourse to the fact that cholesterol is noticeably increased in the blood in all these circumstances, and they hold that it is possible that this increase of blood cholesterol is in part due to a failure of the liver to form bile-salts. Apart from this, the fact that the normal circulation of bile-salts from the liver to the intestine and then back by the portal vein to the liver has been interrupted by the presence of an obstruction, is thought to be sufficient to bring about a steady diminution in the bodily reserves of bile-salts.

In conclusion, these authors have attempted to discover whether there are not frequently variations in the excretion of bile-salts amongst patients suffering from diseases unaccompanied by jaundice. Here, again, caution must be observed because the surface tension of urine can be materially affected by many bodies in addition to bile-salts—chlorides, albumin, and polypeptides being outstanding examples. In many cases of secondary carcinoma of the liver, and during the course of certain acute infections, observations of the surface tension, together with a modified Pettenkofer's reaction, point to the possibility of an excessive excretion of bile-salts. These findings must, however, be accepted with reserve. Still more interesting are certain observations on the effect of injecting an excess of bile-salts into the blood, it being found that by intravenous injection a concentration much higher than that ever observed during biliary obstruction can be produced without any accompanying pruritus or bradycardia.

◆

ACTIONS AGAINST GOVERNMENT DEPARTMENTS.

Government departments are far from enjoying a good press at the moment. Judges abuse them in well-reported phrases; Prof. J. H. Morgan has been attacking them in two articles in a popular evening newspaper; the Lord Chief Justice is understood to be devoting the Long Vacation to preparing for publication a book in criticism of bureaucracy. Though it is not unknown at public dinners for the civil service to hear itself praised for its competence, integrity, and self-effacement, there are plenty of cases (especially during war time) where Government departments have deserved the condemnation they have received. In one sense bureaucracy is increasing and must increase. The manifold activities of the Home Office and the Ministry of Health—in such directions as the inspection of factories, the notification of diseases, and the general supervision of health services—are in a measure an infringement of personal liberty. But it is too late to say that Government departments are not to interfere in these matters. On the other hand, the departmental attitude can easily exceed what is reasonable, especially in the absence of legal check. The medical profession may not be specially concerned, but it remembers its difficulties when panel doctors found the Minister of Health exercising not only executive but also judicial infectious disease seems hardly greater than might be expected in a random sample of the child population. All the cases made a good recovery without operation.

ETHYLENE IN THE OPERATING THEATRE.

ETHYLENE for general anæsthesia has not in this country received the welcome with which it apparently continues to be greeted in America, and in the most recent contributions to the subject[1] we find nothing to make our views more favourable towards its use. The writers, having claimed ethylene as "one of our best general anæsthetics"—which for short operations we may grant them as a correct description—proceed to discuss the explosibility of the gas. In saying that this should not be ignored, they find that ethylene "differs very little from ether in this respect," but later demonstrate how great the difference actually is by detailing the precautions that should be observed to avoid explosion during the use of ethylene. Although these precautions are described as "not burdensome," they appear to outweigh any of the advantages demonstrated for the use of ethylene. The system for avoiding danger "available at little expense and trouble" involves insulated copper wire running along the gas tubes, metallic paint for covering the rubber bags (which must each contain about a pint of water), and a moist cloth attached to the metal frame at the back of the apparatus. "Any potential set up by the gas escaping under high tension through the reducing valves or by friction in the rubber tubes is at once grounded before the mixing of the ethylene and oxygen." The outside of the rubber tube is coated with the metallic paint. Within the tube is a bare spiral copper wire soldered to metal at each end. "It has also seemed advisable to solder a connexion to the metallic spiral in the wall of the rubber tube." Before each operation water is run through the tube. The anæsthetist's feet rest on a moist cloth, or he sits on a stool attached to a moist cloth. A special system of grounding must be worked out based on the fact that cement and tile are good conductors, but wood, linoleum, and rubber-covered floors are poor conductors. After studying the precautions required for the safe administration of ethylene according to these authors, we are left in doubt whether the anæsthetist should be best qualified as a fireman, an architect, or an electrical engineer.

PUBLIC HEALTH CONGRESS AND EXHIBITION.

A CONGRESS will be held at the Royal Agricultural Hall, London, during the week Nov. 19th to 24th, under the auspices of the various British municipal associations interested in public health administration. The congress will be formally opened on the Monday with an address by the Minister of Health, and on the afternoon of the same day Sir George Newman will speak on the purpose of the public health services. On Tuesday morning Sir Walter Fletcher will deal with research in relation to public health, and in the afternoon Dr. C. H. Bond with local organisation for the prevention and treatment of mental disorders. Housing and milk-supply will occupy the attention of the congress on Wednesday, the introducers being Mr. E. D. Simon and Mr. Wilfred Buckley. Thursday will be given up to water-supply and sewage, the principal speakers being Prof. W. J. Wilson, of Belfast, Mr. J. H. Coste, chief chemist to the London County Council, and Mr. John Gardner, of the West Riding Rivers Board. On Friday morning the new medical officer of health for the city of London, Dr. W. M. Willoughby, will speak on food protection, to be followed in the afternoon by Mr. R. H. P. Orde on the construction and equipment of hospitals. The final day of the congress will be given up to the subject of town cleansing. Official delegates to the number of many hundreds have been appointed, and their expenses will be paid by their local sanitary authorities. In the congress hall an exhibition will be held throughout the week, conducted on lines similar to that of the Public Works, Roads and Transport exhibit organised for many years past by Messrs. May and Pattisson, of 13, Victoria-street, London, S.W. 1.

FOOT-AND-MOUTH DISEASE.

FOOT-AND-MOUTH disease is of special interest to the pathologist, as its virus readily passes the pores of a fine porcelain filter, and the susceptibility of the guinea-pig to its action makes the disease a favourable subject for experimental research. The report[1] which has just appeared deals almost exclusively with the disease in small laboratory animals. Improved accommodation for large farm animals has, however, now been completed, and the experimental results obtained with guinea-pigs can be further tested on cattle, sheep, and pigs. The work on which the report is based (set out in three appendices) has been carried out at the Laboratory of the Ministry of Agriculture by Dr. F. C. Minett, at the Lister Institute by Dr. H. B. Maitland, Dr. T. Hare, Mrs. Y. M. Burbury, and Mrs. M. C. Maitland, and at the National Institute for Medical Research by Mr. J. A. Galloway and Dr. S. Nicolau. Mention is also made of research undertaken at the Lister Institute by Prof. A. Ciuca, of Bucharest. A fourth appendix contains a bibliography of work published since the last report appeared. An introduction contains brief reference to important recent work in other countries.

Lebailly and Vallée have noted the early appearance and rapid decline of infectivity in this disease in cattle, and the report contains evidence that active virus cannot as a rule be detected in the lesions of guinea-pigs beyond the third or fourth day after inoculation, though it was found by Dr. Hare in the apparently healthy skin of the ears as late as the tenth day. The results are similar to those obtained by Reppin who could not recover virus from the mouth in cattle later than the eleventh day after infection. Such observations contrast with the prolonged infectivity of the skin and mouth lesions and of the bone-marrow in the dead body, which have been shown to retain active virus for several weeks or even months if the animal has been killed during the infective period and the carcass kept at a low temperature. The viability of the virus on inanimate objects has been further investigated, and survival in vesicle fluid dried on glass and kept in a desiccator at 18° C. for at least two years is recorded. When dried on bran and kept under more natural conditions in the open air of the laboratory the virus has been found active after 40 weeks. Existing evidence therefore points to fomites rather than carriers as the reservoir of infection. Dr. Minett has tested the disinfectant action of a large number of substances, and finds that both acids and alkalis when highly diluted are very destructive to the pure virus; in the presence of organic matter they are much less effective. A 1 : 1000 solution of formalin sprayed on hay was capable of disinfecting it without making it unpalatable as fodder. Mrs. Burbury found that a temperature between 50° and 60° C. rendered inactive the virus contained in liquids, and that an orderly relation existed between temperature, time, and the concentration of the virus similar to that found in the case of bacterial emulsions. The duration and degree of immunity of the guinea-pig and the factors responsible have been examined, and a fairly close relation between the content of antibodies in the blood and the degree of resistance of the animal has been found to exist. It was recorded in an earlier report that a certain degree of active immunity resulted from inoculation with a vaccine consisting of virus killed with formalin. The effect of such a vaccine on the resistance of guinea-pigs has been studied, and confirmation of the previous results has been obtained.

sputum. He claims that careful attention to these points will enable a correct diagnosis to be made in about 98 per cent. of all doubtful cases. Taking Dr. Brown's criteria seriatim—

(1) It will be noted that for significant hæmoptysis Dr. Brown postulates an amount of blood of not less than a teaspoonful. He thus excludes those cases of "coloured" or "streaky" spit which, except in cases of chronic fibroid phthisis, are usually due to causes other than tubercle. We might add that a hæmoptysis which the patient delights to describe is seldom tuberculous in origin, while one which he strives to minimise or attribute to epistaxis is almost invariably of sinister import.

(2) Pleurisy with effusion should obviously be treated as tuberculous unless some other cause is manifest, while dry pleurisy should at least be regarded as a danger signal.

(3) The significance of râles is usually appreciated, but the old and incorrect teaching that tubercle usually commences in the lung apex may lead to error. The signs of the graver types of phthisis, especially in the young, are usually found below the clavicle. The true apex of the lung is more often the site of abortive disease. A careful examination of the axillary regions may reveal crepitations when the upper half of the lung, both anteriorly and posteriorly, is apparently free. The necessity of auscultation over the lateral walls of the chest is too frequently forgotten.

(5) The importance of repeated examinations of the sputum for tubercle bacilli cannot be exaggerated. The failure to apply this simple test is responsible for more errors in diagnosis than all other causes put together. If five examinations at weekly intervals yield a negative result, the practitioner may regard the future of his patient with some degree of equanimity. There are exceptions to every rule, and all the circumstances of the case must be taken into account, but the records of any dispensary will show that, provided a conscientious search for tubercle bacilli has failed to discover the bacillus in the first instance, only in rare cases will a positive finding be forthcoming at a later date. Especially where young adults are concerned, experience does not support the statement frequently made that the "T.B. minus" case, failing sanatorium treatment, will later develop into a "T.B. plus" case.

(4) X rays are invaluable in the differential diagnosis of chest diseases, but a poor skiagram is worse than useless. Unless, therefore, a first-class apparatus and a skilled interpreter are available, the general practitioner will be compelled to rely on the symptoms, physical signs, and bacteriological tests. A history of exposure to infection obviously indicates the need for special care, but whenever possible a radiographic examination of the chest should be made, for, as Dr. Brown rightly insists, it is only in the absence of each of the five criteria that pulmonary tuberculosis can be excluded with confidence.

THE STYPTIC EFFECT OF TRANSFUSED BLOOD.

It is generally agreed that blood transfusion is the most effective means of combating bleeding which occurs as a manifestation of the "hæmorrhagic diathesis." That this transfusion should have a beneficial effect by replacing lost blood is obvious, but it is far from clear why it should also stop the hæmorrhage, either for a time or permanently. The assumption has been that its hæmostatic effect is due to the introduction of thrombocytes or platelets into the circulation of the bleeder, but in considering this it has to be remembered that although most patients with manifestations of the hæmorrhagic diathesis show a thrombopenia, they do not all do so. Many a case has been reported in which bleeding ceased without any increase in the number of the platelets, and there are even records of hæmorrhage persisting despite the presence of platelets in fair numbers in the circulating blood. Evidence against the supposed hæmostatic activity of the transfused platelets is brought forward by Dr. Heinrich Engel,[1] of Prague, as a result of observations made in the course of treating four thrombopenic patients by blood transfusion. He found each time that within a few hours of transfusion the platelet count of the recipients had fallen to its original low level. In one case observations were made during and for 24 hours after the transfusion. In the course of the transfusion the blood was found to contain 28,110 platelets per c.mm.; within one hour they had fallen to 10,460; within six hours to 375, and 24 hours later to 80. Engel concludes that the beneficial results of blood transfusion in the hæmorrhagic diathesis are due primarily to the replacement of blood, which gives the patient a chance to tide over the thrombocytopenic period; he further believes that the transfused blood exercises a styptic effect which, although not due to the intact platelets it contains, may be partly traceable to their disintegration products. A part of the styptic effect, he suggests, may be in the nature of a protein shock reaction, due to the parenteral administration of a foreign protein, and in view of the well-known fact that the coagulability of the blood is increased after the induction of anaphylactic or anaphylactoid states this suggestion appears reasonable. It is supported by the common observation that those transfusions followed by pyrexia and even a definite rigor are particularly effective in stopping hæmorrhage. Since such reactions occur most frequently after transfusion by the citrate method, this may perhaps be regarded as recommending the method when arrest of hæmorrhage is desired.

GALL-BLADDER DISEASE IN THE YOUNG.

Dr. A. H. Potter[2] maintains that contrary to the generally accepted opinion, infections of the gall-bladder occur most commonly in adults under middle age, and that they may be met with quite often in adolescents and young children. In support of his contention he states that statistics of about 25,000 cases of gall-bladder disease collected from the reports of well-known clinics and hospitals show that the average age of patients at the time of operation is 36 years for females and 39 years for males, the interval between the onset of symptoms and the time of operation varying from 3 hours to 39 years. As regards the incidence of gall-bladder disease in very young persons Dr. Potter has collected and tabulated 226 cases in children not above 15 years of age, beginning with Gibson's case, reported in 1722, and ending with August, 1927. Negroes appear to be far less frequently affected than members of the white race. It is noteworthy that while in many instances the symptoms in children were as typical as in adults, children are rather inclined to complain of abdominal pain when gall-bladder disease is present. Dr. Potter contends that the acute infectious diseases of childhood have not received the attention they deserve as factors in the evolution of gall-bladder affections. Whereas in the past typhoid fever was generally the preceding factor in gall-bladder disease, of late years there has been a great decline in the incidence of typhoid, and if this continues the disease will be practically eliminated. On the other hand, there has been a great increase in influenza which Dr. Potter thinks is taking the place of typhoid as a factor in gall-bladder disease. Acute infections of the gall-bladder and cystic duct are usually accompanied by hydrops, which may be transitory or permanent. As the inflammation subsides the cystic duct recovers its function, drainage of the gall-bladder takes place, and hydrops disappears. Four cases in Dr. Potter's own practice occurred in a boy, aged 11, who had had influenza the previous year; a boy, aged 6, who had had scarlet fever 18 months before; a girl, aged 15, who had had influenza in the previous year; and a girl, aged 4½, without any history of illness. This incidence of infectious disease seems hardly greater than might be expected in a random sample of the child population. All the cases made a good recovery without operation.

ETHYLENE IN THE OPERATING THEATRE.

ETHYLENE for general anæsthesia has not in this country received the welcome with which it apparently continues to be greeted in America, and in the most recent contributions to the subject[1] we find nothing to make our views more favourable towards its use. The writers, having claimed ethylene as "one of our best general anæsthetics"—which for short operations we may grant them as a correct description—proceed to discuss the explosibility of the gas. In saying that this should not be ignored, they find that ethylene "differs very little from ether in this respect," but later demonstrate how great the difference actually is by detailing the precautions that should be observed to avoid explosion during the use of ethylene. Although these precautions are described as "not burdensome," they appear to outweigh any of the advantages demonstrated for the use of ethylene. The system for avoiding danger "available at little expense and trouble" involves insulated copper wire running along the gas tubes, metallic paint for covering the rubber bags (which must each contain about a pint of water), and a moist cloth attached to the metal frame at the back of the apparatus. "Any potential set up by the gas escaping under high tension through the reducing valves or by friction in the rubber tubes is at once grounded before the mixing of the ethylene and oxygen." The outside of the rubber tube is coated with the metallic paint. Within the tube is a bare spiral copper wire soldered to metal at each end. "It has also seemed advisable to solder a connexion to the metallic spiral in the wall of the rubber tube." Before each operation water is run through the tube. The anæsthetist's feet rest on a moist cloth, or he sits on a stool attached to a moist cloth. A special system of grounding must be worked out based on the fact that cement and tile are good conductors, but wood, linoleum, and rubber-covered floors are poor conductors. After studying the precautions required for the safe administration of ethylene according to these authors, we are left in doubt whether the anæsthetist should be best qualified as a fireman, an architect, or an electrical engineer.

PUBLIC HEALTH CONGRESS AND EXHIBITION.

A CONGRESS will be held at the Royal Agricultural Hall, London, during the week Nov. 19th to 24th, under the auspices of the various British municipal associations interested in public health administration. The congress will be formally opened on the Monday with an address by the Minister of Health, and on the afternoon of the same day Sir George Newman will speak on the purpose of the public health services. On Tuesday morning Sir Walter Fletcher will deal with research in relation to public health, and in the afternoon Dr. C. H. Bond with local organisation for the prevention and treatment of mental disorders. Housing and milk-supply will occupy the attention of the congress on Wednesday, the introducers being Mr. E. D. Simon and Mr. Wilfred Buckley. Thursday will be given up to water-supply and sewage, the principal speakers being Prof. W. J. Wilson, of Belfast, Mr. J. H. Coste, chief chemist to the London County Council, and Mr. John Gardner, of the West Riding Rivers Board. On Friday morning the new medical officer of health for the city of London, Dr. W. M. Willoughby, will speak on food protection, to be followed in the afternoon by Mr. R. H. P. Orde on the construction and equipment of hospitals. The final day of the congress will be given up to the subject of town cleansing. Official delegates to the number of many hundreds have been appointed, and their expenses will be paid by their local sanitary authorities. In the congress hall an exhibition will be held throughout the week, conducted on lines similar to that of the Public Works, Roads and Transport exhibit organised for many years past by Messrs. May and Pattisson, of 13, Victoria-street, London, S.W. 1.

FOOT-AND-MOUTH DISEASE.

FOOT-AND-MOUTH disease is of special interest to the pathologist, as its virus readily passes the pores of a fine porcelain filter, and the susceptibility of the guinea-pig to its action makes the disease a favourable subject for experimental research. The report[1] which has just appeared deals almost exclusively with the disease in small laboratory animals. Improved accommodation for large farm animals has, however, now been completed, and the experimental results obtained with guinea-pigs can be further tested on cattle, sheep, and pigs. The work on which the report is based (set out in three appendices) has been carried out at the Laboratory of the Ministry of Agriculture by Dr. F. C. Minett, at the Lister Institute by Dr. H. B. Maitland, Dr. T. Hare, Mrs. Y. M. Burbury, and Mrs. M. C. Maitland, and at the National Institute for Medical Research by Mr. J. A. Galloway and Dr. S. Nicolau. Mention is also made of research undertaken at the Lister Institute by Prof. A. Ciuca, of Bucharest. A fourth appendix contains a bibliography of work published since the last report appeared. An introduction contains brief reference to important recent work in other countries.

Lebailly and Vallée have noted the early appearance and rapid decline of infectivity in this disease in cattle, and the report contains evidence that active virus cannot as a rule be detected in the lesions of guinea-pigs beyond the third or fourth day after inoculation, though it was found by Dr. Hare in the apparently healthy skin of the ears as late as the tenth day. The results are similar to those obtained by Reppin who could not recover virus from the mouth in cattle later than the eleventh day after infection. Such observations contrast with the prolonged infectivity of the skin and mouth lesions and of the bone-marrow in the dead body, which have been shown to retain active virus for several weeks or even months if the animal has been killed during the infective period and the carcass kept at a low temperature. The viability of the virus on inanimate objects has been further investigated, and survival in vesicle fluid dried on glass and kept in a desiccator at 18° C. for at least two years is recorded. When dried on bran and kept under more natural conditions in the open air of the laboratory the virus has been found active after 40 weeks. Existing evidence therefore points to fomites rather than carriers as the reservoir of infection. Dr. Minett has tested the disinfectant action of a large number of substances, and finds that both acids and alkalis when highly diluted are very destructive to the pure virus; in the presence of organic matter they are much less effective. A 1 : 1000 solution of formalin sprayed on hay was capable of disinfecting it without making it unpalatable as fodder. Mrs. Burbury found that a temperature between 50° and 60° C. rendered inactive the virus contained in liquids, and that an orderly relation existed between temperature, time, and the concentration of the virus similar to that found in the case of bacterial emulsions. The duration and degree of immunity of the guinea-pig and the factors responsible have been examined, and a fairly close relation between the content of antibodies in the blood and the degree of resistance of the animal has been found to exist. It was recorded in an earlier report that a certain degree of active immunity resulted from inoculation with a vaccine consisting of virus killed with formalin. The effect of such a vaccine on the resistance of guinea-pigs has been studied, and confirmation of the previous results has been obtained.

It has not, however, been possible yet to test the method on cattle in this country. Vallée, however, has reported encouraging prophylactic results in bovines with a formalised vaccine. The differences existing between the three types of virus found in Germany by Waldmann and Trautwein have been confirmed, but, with one exception, the type found in Great Britain has always belonged to the same type as Vallée's O strain. Three methods have been successfully used for determining the type of a virus :—

1. Inoculation of animals recovered from an attack due to virus of a known type.
2. Inoculation of animals protected by a formalised vaccine made with a known type.
3. Inoculation of animals passively immunised with serum of a known type.

Prof. Ciuca, using materials from guinea-pigs, has found complement fixation an effective method of demonstrating the presence of antibodies in the serum of recovered animals and of determining the type of virus present. Further experiments with rats and rabbits have confirmed previous observations showing the slight susceptibility of these animals, and have given no support to the suggestion that the disease is spread by rodents. Mr. Galloway and Dr. Nicolau give an illustrated account of the minute structure of the secondary vesicles on the tongue of guinea-pigs following inoculation of the virus into the sole of the foot. The work was needed because former studies had almost entirely been concerned with lesions at the site of inoculation or with vesicles in a comparatively late stage of the natural disease. The earliest pathological changes detected were small groups of three or four epithelial cells situated at varying depths between the stratum granulosum and the basal layer. The cytoplasm of these cells showed an altered staining reaction, and the nuclear chromatin was condensed into one or more deeply staining masses. At the same time, or very soon after, two or three polymorph leucocytes appeared close to the altered epithelium, but no cellular reaction in the corium could be detected at this early stage. The histological evidence thus brought forward favours the view held by Galloway and Nicolau that the multiplication of the virus is primarily in the epithelial cells. Mrs. Maitland has found that after inoculation of the sole of one hind foot the usual secondary vesicles could be prevented from appearing on the other foot by protecting the latter from pressure with a splint or a cotton-wool pad. On the other hand, if parts of the feet and toes not usually affected were subjected to increased pressure, vesicles appeared on these unwonted sites. Not only was the formation of vesicles controlled in this way, but experimental examination of the skin of the feet showed that the virus had not multiplied in the usual way at the sites of predilection on the soles when vesicles did not occur. The fact that the coöperation of the virus and pressure was needed to produce both the ordinary lesions of the generalised disease and free propagation of the virus in the usual sites is an interesting example of mutual action and reaction of an infective agent and the tissues.

The report shows steady progress in our knowledge of the infective agent, the pathology, and the nature and control of immunity in this important disease.

PROTECTION OF MOTHERHOOD IN SWITZERLAND.

EIGHTEEN years ago Dr. Bernheim Karrer stated in writing that there was nothing which could fairly be described as systematic protection of motherhood and infancy in Switzerland. A good deal of progress has been made in the meantime, and in a recent issue of the monthly bulletin of the International Office of Public Health Dr. Karrer, who is now director of the cantonal day nursery at Zürich, gives a critical survey of the work undertaken for the preservation of maternal and infant life. He still finds his country behindhand in the matter of antenatal supervision, stating that German-speaking Switzerland possesses no such thing as an antenatal clinic except for one or two connected with maternity hospitals. In French-speaking Switzerland antenatal clinics are distinct institutions, but there are very few of them compared with the number of child welfare consultations. Again, while laws are in force which make careful provision for the nursing mother, both in money grants and exemption from heavy work, the pregnant woman may ask to be excused from work in a factory for eight weeks before confinement only at her own expense, there being no financial help to enable her to do so. This poverty of antenatal care is the more unfortunate, since little improvement has been effected in the toll of stillbirths and deaths in the first four days of life during the last 15 years. Whereas the general infantile mortality stands at 56·5, comparing favourably with many other European countries, the mortality of the first four days is 19·2. In other respects, however, strides have been made; pædiatrics is now an obligatory subject in the medical course and examinations, and the study includes hygiene and feeding of infancy. Midwives, who are still the chief counsellors of Swiss mothers, have also had their training stiffened up and lengthened, and health visitors and baby nurses take a year's course followed by examination. Instruction of the public, and especially of mothers, is forwarded by schools for mothers, infant consultations (always conducted by doctors), and travelling exhibitions. The institutions for the care of babies include maternity hospitals, children's hospitals with wards for infants, refuges for mother and child together, baby shelters, day nurseries, and residential nurseries. The nursery at Zürich, of which Dr. Karrer has charge, is a home with 45 beds, attached to the obstetric clinic; it is primarily intended for premature infants, but also admits sick newly-born infants referred from the clinic. Many children are put out to nurse and, though nominally under medical supervision, in some districts the supervision is by no means satisfactory. In Zürich the work is carried out from a child protection office, and is so well done that Dr. Karrer suffers less anxiety on behalf of illegitimate infants who leave the nursery than of those whose parents are poor and improvident. A number of similar voluntary societies, as well as the national organisation "Pro Juventute," do useful work in backing up the State provisions.

ATMOSPHERIC POLLUTION.

THE thirteenth report of the Advisory Committee on Atmospheric Pollution[1] covers observations made in the year ended March 31st, 1927. It is the last of these reports to be issued from the Meteorological Office (Air Ministry), for the work has been transferred to the Department of Scientific and Industrial Research which will from now on coördinate local records and prepare an annual report thereon. This task will remain in the hands of Dr. J. S. Owens, who can be addressed at 47, Victoria-street, London, S.W. 1. In addition to this routine survey special researches are to be directed towards the solution of the scientific problems of atmospheric pollution, and these will come under the Director of Fuel Research, supervised by a committee of the Department, of which Dr. G. C. Simpson, F.R.S., is chairman, and Mr. J. K. Best (Cadbury Bros.), Mr. J. H. Coste (Chief Chemist, L.C.C.), Dr. G. M. B. Dobson, F.R.S. (Lecturer in Meteorology, Oxford University), Dr. R. Whytlaw-Gray (Professor of Chemistry, Leeds University), and Sir Napier Shaw are members. The last named has also expressed his willingness to serve as the first chairman of a standing conference of coöperating bodies which will continue the consultative work of the Advisory Committee. The report, as heretofore, contains a mass of information on the deposit of impurity at 80 different stations in the United Kingdom. Although the good stations continue to show improvement the bad ones remain as bad as ever. The highest deposit of tar as well as of sulphates was at Burnley; the lowest in either category at Southport (Hesketh Park). Newcastle-on-Tyne scored highest for carbonaceous or sooty matter which there may make up 40 per cent. or more of the total deposit, the lowest record being at Rothamsted. Some of the reduction in the deposit of sulphates seems to be due to the increasing use of gas as a fuel. In London and Glasgow from 1914 to 1927 the sulphate deposit has diminished out of proportion to the total. An interesting curve shows the effect of suspended smoky matter in the coal stoppage of 1926 at Stoke-on-Trent; in London the event produced no appreciable effect. It is also clearly brought out in a curve that nearly the whole of the ultra-violet rays of sunlight are cut off by a comparatively small amount of smoke in the air. An interesting account is given of a haze in Norfolk which was found to consist of salt crystals. While the continuance of these detailed observations under the ægis of the Research Department is assured, it must be no small satisfaction to those who have taken a share in this laborious survey for so many years that there will now be fitting opportunity for organised research into the scientific problems involved. The time is ripe for drawing conclusions from an immense wealth of material.

SYNTHALIN IN DIABETES.

THE use of insulin in diabetes has certain disadvantages. Although the necessity for injection encourages exact dosage, so far as quantity is concerned, it does not reproduce the conditions of physiological secretion, and where large doses are given the immediate result of its administration may be an excessive reduction of the blood-sugar, followed later by hyperglycæmia when absorption of carbohydrate from the intestine is well under weigh. From almost every point of view it would be preferable to use a drug which could be given by mouth and absorbed slowly with other contents of the alimentary canal, and high hopes were raised a couple of years ago when it was suggested that insulin might find a supplanter in the new German preparation called synthalin. This drug had not been invented ad hoc, but had been evolved during a series of investigations on parathyroid tetany in which it was found that guanidine caused a fall in blood-sugar. This happened only at the cost of poisoning the animal, but aminobutyleneguanidine proved less toxic, and synthalin—so far the most satisfactory of this series of substitution products—was recommended as relatively innocuous.

Synthalin contains two molecules of guanidine, joined by ten CH_2 groups, and its action is shown to be wholly different from that of insulin, as it lacks the essential power of promoting the oxidation of glucose. The first accounts of its effect on patients were nevertheless distinctly favourable. Frank, Nothmann, and Wagner[1] reported that sugar disappeared from the urine in mild cases of diabetes and that the blood-sugar was lowered, though not reduced to normal; in severe cases the dose of insulin could be reduced. They admitted that synthalin did not act quickly enough to benefit patients in coma, and they did not approve its use for children. The Medical Research Council arranged for tests in this country, and preliminary reports from many British hospitals were published in THE LANCET about a year ago.[2] These included investigations carried out at St. Bartholomew's by Dr. George Graham and Dr. G. C. Linden, who have now published a more detailed account of their work.[3] In 8 patients out of 12 they found that synthalin caused a very definite and apparently beneficial change in the carbohydrate metabolism. In one of the eight 50 mg. of the compound replaced 10–15 units of insulin without the blood-sugar exceeding the normal limit, but in the remaining four it afforded no practical benefit. These results are not so good as those of the early workers, but they are better than some of the others reported. The mode of action, as Graham and Linden point out, is still obscure. Insulin is a natural secretion, and will always lower the blood-sugar if enough is given; synthalin is a foreign chemical and has no action on sugar in vitro. They consider that synthalin must influence the carbohydrate metabolism by modifying cellular activity, and that this action is possibly a minor part of the more general effect that shows itself in toxic symptoms. It may work by depressing the power of the liver (increased in diabetes) to deaminise amino-acids, or its action may be regarded as a slight degree of a poisoning which when severe causes nausea, vomiting, pain, and jaundice. It is, of course, possible that its effect on carbohydrate metabolism is distinct from its toxic action, and that its failures are due to some idiosyncrasy in the patient. If this is so, it offers a parallel to salvarsan, which does not itself kill spirochætes, but causes the body to generate a lethal substance, and which also fails in some patients, whilst on occasion it produces effects comparable with those of synthalin. The toxic properties of synthalin are, however, a very severe drawback to its employment, for few patients who have experienced them will ever run the risk again. They occurred in 5 out of the 12 cases treated in this test. As prophylaxis against them, Frank has recommended that the dose of synthalin be withheld every fourth day, and A. Adler uses with each dose grs. 3 of sodium dehydrocholate ("decholin") which increases biliary secretion and may perhaps accelerate the excretion of synthalin from the liver.[4] This preparation was not tested at St. Bartholomew's Hospital, but Graham and Linden suggest that it should always be used, and that the dose should be carefully limited by starting with small amounts and gradually increasing them.

The fate of the sugar which disappears is unknown. It is not found in the liver or muscles as glycogen, and the lactic acid which is formed quickly vanishes again. Synthalin may merely destroy the sugar in the blood as yeast does in the stomach, but the appearance in one patient of a severe ketosis three days after the suspension of treatment suggests that the disappearing sugar was at least exerting an anti-ketogenic influence. To sum up, Graham and Linden say that there is no good evidence that the patients are really the better for having synthalin. Patients who need insulin had better use the natural product if possible; the new synthetic rival has a place only when there is a reason against injection.

HARVEST BUGS.

WE have in this country so few animals which bite and prick and sting with serious results that we make a good deal of fuss about beasts which are hardly worse than interesting. And now that the season of sitting about in the open air is with us, many people who respond vigorously to its attentions will lament the existence of the harvest bug or mite. They should also read the account of the animal and its allies which is given by Mr. Cecil Warburton in *Parasitology* (July, 1928, p. 228). There are about a dozen species of mites which afflict man in much the same way in different parts of the world; in all cases it is the larva alone which is parasitic and, as the adults are hardly known, the systematics of the subject are considerably muddled. The only one of which the life-history may fairly be said to be known is the Japanese *Trombicula akamushi*, which is something more than an annoyance because it transmits the river fever or tsutsugamushi disease. The larva in this instance is found abundantly on field mice and readily attacks dogs, cats, guinea-pigs, and other animals besides man. After much labour Miyajima succeeded in rearing adults and found that they were neither parasitic nor predaceous but can be reared on such food as potatoes and melons and appear in nature to live on various plants; moisture is essential. Our national harvest bug is also a larva; none of the few people who have tried has succeeded in rearing the adult form, so that we have no means of knowing where and how it lives. More extraordinary still, perhaps, is the fact that those who study wild mites have failed to find one which may reasonably be supposed to be the missing parent. Obviously there is room here for an interesting piece of work. Dry grassy places, chalk downs, and the like, seem to be the animal's favourite habitat; it evidently lives somewhere, possibly underground or in the nests of mice. Meanwhile the best treatment for those who are particularly susceptible seems to be a complete change of clothes and a bath.

SCARLET FEVER ANTITOXIN.

WHEN this antitoxin was first introduced the important question was whether we had, or had not, found a useful agent in the treatment of scarlet fever. That question has been answered in the affirmative. Though no efficient serum appears to be yet available for combating the septic complications such as adenitis, otitis, or mastoiditis. there is now general agreement in many countries that for the treatment of uncomplicated attacks of scarlet fever caused by the toxin of the scarlet fever streptococcus, and for the protection of susceptible individuals who have been exposed to infection, antitoxin is potent and specific. Its use is now widespread. The main interest has therefore shifted to the question of dosage and standardisation. Of the methods of standardisation which have been tried, three need human subjects—viz., the Schultz-Charlton test, passive immunisation, and the Dick method of "skin neutralisation"; in two methods animals are used—viz., the Wadsworth-Kirkbride skin neutralisation in goats and the Parish-Okell rabbit test. If a test involving the use of animals has an error no greater than those needing human subjects, the animal test will presumably gain acceptance. The various methods are being compared in many laboratories but no critical comparison appears yet to have been published. Dr. R. Cruickshank elsewhere in this issue concludes in favour of the skin neutralisation method in human beings and the rabbit test, though his own careful observations on the duration of passive immunity show that this also is a good method of titration, for the effect of a dose of 2·5 c.cm. can be clearly differentiated from that produced by twice the dose, the patients in the latter group remaining negative to the Dick test for a longer period. This method would provide those in isolation hospitals with a means of testing the serum they use, for 5 c.cm. of a good serum will, as he[1] and D. McClean[2] have shown, keep the majority of patients negative to the Dick test for seven to ten days and will protect contacts from infection with scarlet fever. Parish and Okell[3] state that an average concentrated serum will in a dose of 0·25 to 1 c.cm. protect rabbits against the acute illness produced by the injection of culture of scarlet fever streptococcus. This method they use for measuring the strength of sera. Both Cruickshank and R. E. Dyer[4] discuss the difficulties of the skin neutralisation test. Not all Dick-positive subjects are suitable for the test, because of serum sensitiveness, and the readings are not easy. In U.S.A. an official unit based on this method has been fixed and a minimum content of antitoxin prescribed. No English official unit has yet been adopted. Meanwhile, the general experience in England that the sera available are efficient in the treatment of scarlet fever and for the passive protection of contacts is evidence that the methods of titration of these sera in use in the various serum institutes are serving their purpose and ensuring supplies of satisfactory sera.

BRITISH MEDICAL ASSOCIATION.

ANNUAL MEETING AT CARDIFF.

(Continued from p. 250.)

SECTION OF SURGERY.

UNDER the presidency of Prof. A. W. SHEEN and later of Mr. A. J. WALTON, a discussion on the

DIAGNOSIS AND TREATMENT OF SPINAL CORD TUMOURS

was opened by Mr. DONALD ARMOUR, who limited himself to tumours arising from the cord, the spinal nerve roots, and the meninges, and chondromata of the intervertebral disc. Clinically they caused a paraplegia by compression. More than three-fourths were extramedullary and the intradural were more frequent than the extradural by three to one. Of intradural tumours about two-thirds were dorsal or dorsolateral in position. The course of the disease was usually slow and chronic and divided into three stages: (1) of root symptoms, usually unilateral; (2) of Brown-Séquard paralysis; (3) of complete compression, paraplegia, or bilateral paralysis. The symptoms generally appeared in the following order: Peripheral pain, increase of reflex activity below the point of compression, paralysis, loss of sensibility, and loss of reflex activity with flaccid paralysis. The commonest early symptom was localised, recurring and persistent pain, referred to the course of the nerve involved and attributed to innumerable conditions in the body and limbs. Pain in the back might be the only complaint for a long time, especially with lumbosacral and cauda equina growths. Pressure on the sensory tracts of the cord might cause pain in remote parts of the body before any motor or sensory changes could be discovered. Paræsthesiæ of various kinds might occur, at the level of the tumour, from root irritation; above the level, from pressure of the held-up cerebro-spinal fluid, or from sympathetic involvement; or below, from irritation of sensory tracts. Objective sensory changes were usually absent in the early stages and later depended on the amount of compression or destruction of the tracts. In extramedullary tumours there was some dissociation of sensations below the level of the tumour, while all types of sensation were equally involved in intramedullary growths, in which also the maximum sensory disturbance was often at and below the segmental level. Tactile sensation was less affected than pain and temperature. In tumours of the conus and cauda equina the sensory disturbance was usually bilateral and asymmetrical. Subjective motor disturbance usually followed subjective sensory symptoms and was progressive. In high tumours the order of limb involvement was almost always: homolateral upper limb, homolateral lower limb, contralateral lower limb, contralateral upper limb. The irritative stage, with tremor, muscular tension, and spasms was generally over by the time the patient came for examination, or was masked by a degenerative paralysis of the corresponding muscles with a diminished tendon reflex. When the tumour began to exert further pressure on the cord direct and indirect spinal symptoms appeared and were of great diagnostic value. Very often a minimal stimulus produced the "mass reflex." Bladder loss usually preceded rectal loss by some time. The pathological effects of the actual pressure on the cord were extraordinarily limited, as was shown by the recovery after removal of a large tumour. Paraplegia in flexion followed paraplegia in extension which might, however, be a very short stage.

Localising Symptoms.

Nystagmus might appear in high cervical tumours and bulbar symptoms occurred occasionally. Intense pain up the back of the neck and head might cause a clinical picture suggestive of caries or spasmodic torticollis. Involvement of the phrenic roots might cause diaphragm paralysis.

In lower cervical tumours four root syndromes might appear—Erb-Duchenne type; a middle type with atrophy of the triceps; Aran-Duchenne type and Dejerine-Klumpke type.

Lower dorsal tumours might simulate abdominal disease and lumbar tumours might show multiple root signs with atrophic paralysis. Tumours of the cauda equina caused intense pain radiating over the sacrum, perineum, and back of legs, and trophic sores were common.

Atypical clinical forms were of four kinds. Those with purely medullary symptoms showed paraplegia without any signs of root involvement. Those with purely root symptoms were like ordinary neuralgias. When there were multiple tumours, two root syndromes were superimposed. The vertebral form was marked by intense and diffuse pain and was often diagnosed as Pott's disease.

There was no symptom which occurred exclusively with any one kind of tumour. The symptoms differed in sequence, duration, and time of onset according to the localisation of the growth. A short history was in favour of the more rapidly growing extradural variety. Bony changes were rarely seen in intradural tumours and were common in extradural. Other features of extradural tumours were sensitiveness to pressure over the spine and absence of root pain and xanthochromia; lumbar puncture might cause sudden and marked increase in symptoms. Great excess of protein in the lumbar fluid combined with completely normal cisternal fluid or a "reversed" Brown-Séquard syndrome was in favour of an extradural growth. As a rule, intramedullary tumours were characterised by less frequent root pains, less spastic paraplegia, and more common amyotrophic phenomena, a more marked alteration in painful and thermal sensibility and a typical and clearly shown dissociated anæsthesia. In favour of a diagnosis of extramedullary tumour was: a preliminary stage of root pain, slow but continuous development of alteration in motor and sensory function, a growth in breadth rather than in length, fairly long persistence of a Brown-Séquard syndrome, marked spasticity persisting after the appearance of complete paraplegia with Babinski's sign; symptoms of motor root irritation and absence of signs of atrophic degenerative paralysis, and of trophic troubles, and the "loculation syndrome" in the cerebrospinal fluid.

Combined cisternal and lumbar puncture was a diagnostic aid revealing below an area of compression, xanthochromia, increased protein and other substances, and occasionally spontaneous coagulation. The replacement of cerebro-spinal fluid by air caused no nausea, pain, or collapse in cases of spinal block. Lipiodol injection was not very reliable, and there might be sensory lipiodol dissociation; its greatest field of usefulness was where the sensory level was not well defined.

There was only one treatment—operation—which demanded correct diagnosis and precise level localisation. Segments of the cord did not correspond with the vertebræ of the same name, and there were also individual differences. The operation of choice was laminectomy as developed by Victor Horsley, with the patient in the lateral position, under intratracheal ether. (Mr. Armour then described the technique in detail.) French authorities were more enthusiastic than others in the use of X rays and radium for inoperable growths, but even they were cautious and warned against exaggerating the curative value.

Dr. G. **RIDDOCH** said that diagnosis must ultimately rest on the existence of a progressive paraplegia with signs pointing to root involvement. Remote signs might be absent at a stage when diagnosis was quite possible, or focal signs might be absent throughout. Clinical features came first in diagnostic significance, followed by investigation of the cerebro-spinal fluid and vertebral signs and, in selected cases, by other methods for determining the patency of the subarachnoid space. The paraplegia developed in a certain definite way; the first stage was a spastic paraplegia in extension, with a weakness that was more flexor than extensor, and which appeared more in the lower limbs, with downward pointing of the foot and toes. The reflexes were all increased and Babinski's sign was present. Homolateral extension of the whole limb might be evoked by stimulating the leg below the knee, and the gait was spastic. In the second and graver stage, of paraplegia in flexion, the flexion reflex dominated the reflex picture and could be obtained by stimulation of any part of the limb, and the mass reflex might be evoked. In the third stage there was flaccid paralysis. The diagnosis of the level of the growth was made primarily on focal signs, which might be of root or of segmental origin. The former pointed definitely to the segment involved, but the latter did not. Motor signs were usually of less value. Diagnosis was most difficult when there were no focal signs and reliance had to be placed on the often equivocal sensory phenomena and the motor and reflex signs, which were not much help. It was necessary to ascertain the point where normal sensibility changed into abnormal, and not merely the highest limit of complete anæsthesia; moreover, the obliquity of the fibres had to be taken into consideration. The appreciation of tuning-fork vibration was often valuable and might be impaired when the posterior columns were involved. On the whole, intramedullary tumours were more often cervical or lumbosacral in location and extramedullary ones about the regions of the enlargements. With the former, remote and focal signs appeared more or less together, while with extramedullary growths the focal signs might appear long before there was any paraplegia.

Lipiodol Injections.

Sir **PERCY SARGENT** showed lantern slides of different varieties of tumour and X rays of lipiodol injections. Lipiodol, he said, sometimes caused severe root pain and might have serious after-results. When successful it was very useful, but the better the neurologist the less often would it be necessary and it should be used less rather than more. Intramedullary tumours usually extended over many segments, producing an elongated block, in contrast with the local block of extramedullary growths. By a cisternal injection and a lumbar injection with the patient inverted, it was possible to map out an area of block. The prognosis of patients with intramedullary tumours was not hopeless—he had seen three recoveries. The operative mortality-rate was very low; the worst areas were between the second and fifth dorsal, where serious cardiac, gastric, or intestinal disturbance might be caused. The excellent recovery depended on the facts that compression had been very slow, that the bladder function was usually involved very late and very slightly, and that bedsores were very rare; there were therefore no septic complications.

Mr. **LAMBERT ROGERS** recorded six cases of spinal tumour from the Welsh National School of Medicine, one in a girl of 16, who had made a remarkable recovery. The tumour had contained many psammoma bodies and also masses of true bone, a very rare finding which afforded evidence of the essential similarity of cranial and spinal meningiomas and supported the mesoblastic derivation of membranes.

Mr. G. **JEFFERSON** said that his experience of spinal cord tumours was that they were practically painless and patients complained of spastic paraplegia. The syndrome of cord compression followed in a definite sequence, first a disturbance of motor power in the legs and then sensory changes of a particular kind, notably dissociation. He then showed a number of charts demonstrating the results of investigating the cerebro-spinal fluid by the Queckenstedt method.

The Importance of Early Diagnosis.

Mr. **WILFRED TROTTER** spoke for the common man, and said that the diagnosis was often missed in the early stages, especially when the disease began as unexplained pain, which was almost always diagnosed by some meaningless phrase, varying from year to year with the fashion—*neuritis, sciatica, arthritis*, fibrosis. That was the form in which spinal tumour came before the panel doctor. The commonest tumour was the neurofibroma, and this essentially began with root pain, without any physical signs. If it were then diagnosed, treatment would be early and almost invariably successful.

Mr. H. ADAMS quoted a case of psammoma of the sixth dorsal region, which began as a painless limp. He suggested that the neurofibroma type might be the cause of pain, while the psammoma and endothelial type of tumour was the cause of spastic paraplegia.

Mr. STANLEY FOSTER recorded several cases with no paraplegia, only pain; one had been diagnosed as neurasthenia, and another as Pott's disease and disseminated sclerosis successively.

Mr. R. BROCKMAN said that cases of unexplained pain were the most difficult to diagnose, and instanced one woman with unilateral pain radiating from the lumbar region round to the pelvis. She had had an inflammatory mass removed from her abdomen and a subsequent nephrectomy without relief, and died suddenly after a profuse hæmorrhage from a spinal tumour. Cases of "curious pain" should always suggest spinal cord tumour.

Mr. WALTON said that the slower the course the better the prognosis, as the ultimate results depended less on the presence of a tumour than on the damage it had done, which was proportional to the rapidity of its growth. All cases should be operated upon at once. He agreed with Mr. Armour's technique. What operative risks there were were the accidental risks of all operations.

TREATMENT OF GANGRENE.

Mr. SAMPSON HANDLEY (London), in opening the discussion, said he proposed to confine his remarks to more recent methods of vasomotor surgery in relation to gangrene, and gave a brief history of the subject. He described Leriche's method of performing periarterial sympathectomy and stated that this surgeon had had successes in various conditions, but he did not perform his operation for gangrene. According to Prof. Leriche, after sympathectomy there is a local contraction of the artery, and for some hours pulsation is feeble and the limb is colder than its fellow. This is followed by elevation of the temperature of the limb and of the arterial pressure, and by increased amplitude of the pulse for from three to four weeks.

The speaker then drew attention to his method of alcohol injection, which he believed was a definite advance on Leriche's operation, and claimed that in certain cases it will avert threatened gangrene, or arrest the spread of senile gangrene already present, and so obviate amputation. The technique used is to expose the femoral artery in Hunter's canal for 1 to 2 in. With the finest possible hypodermic needle 2 to 3 minims of alcohol are injected at four points spaced round the artery, the needle being inserted obliquely and nearly parallel to the vessel. When the injection is complete a whitish band about ½ in. wide should be seen round the artery, but no constriction takes place. The effect of alcohol injection is that the foot in successful cases becomes warmer almost at once and the vasodilatation may last for a year or more, whereas it is stated to pass off in a few weeks after Leriche's operation. Mr. Handley mentioned some criticisms of the method and stressed the difficulty of making a proper selection of cases at present. In regard to indications, he would advise it strongly in cases of threatened or incipient gangrene of a lower limb, but would prefer to employ it in the prodromal stage. He considered it useless in Buerger's disease and of doubtful value in Raynaud's disease. Finally, he claimed that alcohol injection was a distinct advance on Leriche's operation, and appealed to medical men when first consulted for symptoms of arterial dystrophy to allow vasomotor surgery a fair field in its attempts to avert the onset of gangrene and the loss of a limb.

Mr. PHILIP TURNER (London) said he would confine himself to the clinical aspects of periarterial sympathectomy, which he had performed eight times, twice by operation and six times by alcohol injection. Of these, three were very striking successes which he narrated, three were temporarily improved, and two, whose general condition was very bad, died. Mr. Turner pointed out that following sympathectomy the following clinical effects were seen whatever their cause—namely, increased warmth of the foot, relief of pain, disappearance of swelling, rapid formation of a line of demarcation, and improvement in general condition. Mr. Turner said this operation was a valuable addition to amputation, which might be avoided in 25 per cent. of cases and delayed in 50 per cent., and in his opinion it is particularly indicated in early cases of senile gangrene and should be carried out as soon as the diagnosis is made.

Mr. E. G. SLESINGER (London) could not agree that sympathectomy acted by dividing the vasoconstrictor fibres; all modern evidence, he said, was against this. He suggested that what were divided were the afferent sensory nerves of the arteries, and the effect of sympathectomy was due to breaking the reflex arc. He discussed arterial pain and compared the pain of *angina pectoris* and *abdominis* with that of incipient gangrene. In his experience the operation succeeded when there was reflex spasm in addition to organic narrowing. He could see no advantage in the method of alcohol injection over sympathectomy which he had performed 25 times with no mortality. Finally, he urged that sympathectomy should be tried in all painful cases of organic vascular disease, since it would relieve pain almost certainly and might, in addition, improve the circulation.

Mr. W. A. COCHRANE (Edinburgh) had treated cases of gangrene by exposing the main artery and rubbing it with gauze, and had had successes. He considered it of no value in endarteritis obliterans, but had found temporary benefit in varicose ulcers.

Sir WILLIAM WHEELER (Dublin) had no experience of alcohol injection. He related cases of thromboangiitis obliterans in which he had performed sympathectomy with no benefit and with no relief of pain, and he stressed the importance of removing the whole sheath.

Mr. R. StL. BROCKMAN (Sheffield) put in a strong plea for alcohol injection on the ground of simplicity which brought it within the compass of every surgeon. He considered it of value as a preliminary to amputation.

Mr. HANDLEY, in replying, mentioned the possible danger of absorption of toxic materials from the dead gangrenous part as the result of vasodilatation after operation.

FALLACIES OF X RAYS IN ABDOMINAL DIAGNOSIS.

At a discussion held jointly with the Section of Radiology, Mr. H. J. PATERSON (London) began by pointing out that medicine, being essentially an art, laboratory methods can never replace clinical observation. The chief fallacies as regards surgery might be grouped as: (1) those *incidental* to X rays; (2) those due to errors of technique; (3) those of misdirection; (4) those of interpretation. Under (1) the speaker said that X rays exaggerated stasis and a better method of estimating this was the charcoal method; a further fallacy under this head was spasm. Duodenal ulcers were seldom shown by X rays, but often inferred when not present, and whether gastric ulcers were shown depended on their size and depth. Under fallacies of technique were instanced the need for exposures in different positions, and the importance of having the stomach well filled with barium. *Fallacies* of misdirection consist of diverting the attention to some abnormality of less serious import than the main disease. The last group of fallacies of interpretation were *numerous* and cases were mentioned of error in connexion with gall-stones, ureteric calculi, appendicitis, gastric ulcer, adhesions, &c. Mr. Paterson said an insidious fallacy was the claim that healing of a gastric ulcer could be shown by X rays. Ulcers are stated to heal in a few weeks after alkali treatment, but is the evidence good enough considering the intermittent nature of the disorder? Finally, the opener said he did not question the utility but the infallibility of X ray diagnosis.

Dr. F. HERNAMAN-JOHNSON (London) stressed the advantage of X rays over charcoal in localising stasis of the bowel. In regard to spasm he would hold that spasm persisting after full doses of belladonna shows some lesion in the alimentary tract. Failure to find organic lesions does not prove their non-existence, and a negative X ray can only exclude gross deformity. He objected to including fallacies of misdirection, as it is important to demonstrate any definite lesion. Fallacies of interpretation must always remain and no radiologist could differentiate on X ray evidence only between an inflammatory lump and carcinoma. It is important for radiologists to indicate which of their deductions depend on X ray findings and which on examination and history. The speaker pointed out the importance of not calling an appendix normal because X ray examination does not incriminate it, and stated that a pelvic cæcum which does not rise on a barium enema and which contains residue after 24 hours often means appendicitis.

Dr. A. F. HURST (London) said the diagnosis of gastric and duodenal ulcer depended largely on the skill of the radiologist and in experienced hands should be right in 90 per cent. of cases. He would never diagnose gastric or duodenal ulcer without X ray evidence and the same applied to carcinoma. In his opinion, if there was no obstruction, all gastric ulcers would heal if treated medically, provided treatment was sufficiently long and thorough, and their healing could be shown by X rays. Dr. Hurst mentioned the fallacy by which a not uncommon diverticulum in the region of the cardia is mistaken for ulcer.

Mr. W. MCADAM ECCLES (London) stressed the importance of a complete radiological examination, and mentioned cases where incomplete examination had led to unnecessary removal of the appendix.

Prof. A. FULLERTON (Belfast), after pointing out the necessity of piecing together the evidence of various investigators in order to make a diagnosis, discussed the value of stereoscopic X rays in differentiating phleboliths and calcareous glands from urinary calculi.

Sir WILLIAM WHEELER appealed to radiologists to follow-up operations performed on cases they had seen, and said it was important not to give too definite a negative report lest further observation of the case might be discouraged. Personally, he thought there was no such thing as medical treatment for chronic gastric ulcer.

Mr. RENDLE SHORT (Bristol) spoke of the value of coöperation between radiologist and surgeon and of the difficulty of proving a negative. In his experience, if the clinical diagnosis and the X ray diagnosis differed, the X ray diagnosis was more often the correct one.

Dr. T. I. CANDY (Newport) said that cases were often sent for barium meal examination too casually and without adequate notes. He asked that radiologists should be given proper data and that it should be remembered that they were often the only units of the team whose opinion was committed to paper and could be held against them.

The Chairman, Prof. A. W. SHEEN (Cardiff), spoke of the effectual cooperation that existed in his clinic, and said that negative X ray findings were often as important as positive ones.

Dr. O. LEWELLIN RHYS (Cardiff) likened the radiographer of some years ago to the race-course tipster who had to name the winner before the race, and was abused if he failed to do so. Nowadays, the surgeon must bear his share of responsibility for a preoperative diagnosis.

SECTION OF PATHOLOGY AND BACTERIOLOGY.

Sir THOMAS HOUSTON took the chair at a discussion on the

BACTERIAL FLORA OF THE INTESTINE IN HEALTH AND CHRONIC DISEASE

which was opened by Prof. J. CRUICKSHANK (Aberdeen), who surveyed the bacterial contents of the newly born and traced the changes that occur as age advances. He pointed out that the meconium is sterile, but *organisms appear in small numbers* in the first 24 hours after birth. During the first few days the organisms most frequently found are the *Staph. albus*, *Strept. fæcalis*, and members of the *B. coli* group. In the first sample of the meconium free fæces an organism of the *B. bifidus* type, appears. This latter organism increases in number and replaces other organisms to a large extent. If the child is breast fed, the *bifidus* type constitutes 95 per cent. of the organisms present. In artificially fed infants the predominant organisms are of coliform type. The fæces of breast-fed infants are distinctly acid in reaction, while those of artificially fed infants are alkaline or neutral. *B. bifidus* and organisms of the *acidophilus* type can survive exposure to highly acid fluids, which destroy coliform organisms. Thus the bacterial content of the intestine is related to the chemical reaction. Spore-bearing organisms are absent from the suckling's stool for the same reason. When breast-feeding is over opportunity is offered for the invasion of the alimentary canal by many organisms. The intestinal organisms have been grouped into two types, proteolytic and saccharolytic. Experimentally it has been found that a high carbohydrate diet gives a flora rich in *bifidus* and *acidophilus*, whereas a high protein diet gives a predominance of coliform organisms and spore bearers. Lactose appears to be the determining factor in the production of the saccharolytic type of flora. In 1915 Torrey reported favourably upon the use of lactose in typhoid fever, a most marked change occurring in the bacterial flora. The same treatment has been applied to conditions of intestinal origin in children associated with lassitude and anorexia with diarrhœa or constipation, in which there is proteolytic intestinal flora. A quicker transformation of the flora is achieved by combining lactose diets with cultures of *acidophilus* organisms. Prof. Cruickshank attributed the action of the sugar to its being attacked by *B. coli* and *B. welchii*, the various acid substances produced offering a suitable pabulum for the growth of *B. acidophilus*. This is suggested by the fact that direct inoculation of fæces into milk gives abundant growth of *B. coli* and enterococci in the first few days, but at a later date vigorous growth of *B. acidophilus* occurs. Sugars other than lactose have been tried but the above results have not been obtained. Starchy foods, however, tend to change the flora. The administration of animal proteins, on the other hand, produces a marked proteolytic or putrefactive flora. The speaker emphasised that to change the type of bacteria to the acid variety large quantities of lactose must be used, together with an *acidophilus* culture capable of surviving in the intestine. He further declared that the types of intestinal flora are most probably the result of abnormal intestinal conditions and not the cause of them. Dealing with the subject of auto-intoxication, he said that nothing had emerged from chemical or bacterial research in recent years to support the view that harmful substances are elaborated by bacteria in the intestine and then absorbed. It had been shown that a closed-off loop of intestine may contain very toxic material, but this is incapable of deleterious effects until the intestinal mucosa is grossly damaged. Experimentally produced intestinal obstruction in dogs tended to show that the resulting toxæmia is not so much due to bacterial disintegration above the obstruction as to mechanical disturbances below. In chronic ulceration there is frequently no evidence of intestinal toxæmia in many cases, although it might unexplained pain, which was almost always diagnosed by some meaningless phrase, varying from year to year with the fashion—neuritis, sciatica, arthritis, fibrosis. That was the form in which spinal tumour came before the panel doctor. The commonest tumour was the neurofibroma, and this essentially began with root pain, without any physical signs. If it were then diagnosed, treatment would be early and almost invariably successful.

Mr. H. ADAMS quoted a case of psammoma of the sixth dorsal region, which began as a painless limp. He suggested that the neurofibroma type might be the cause of pain, while the psammoma and endothelial type of tumour was the cause of spastic paraplegia.

Mr. STANLEY FOSTER recorded several cases with no paraplegia, only pain; one had been diagnosed as neurasthenia, and another as Pott's disease and disseminated sclerosis successively.

Mr. R. BROCKMAN said that cases of unexplained pain were the most difficult to diagnose, and instanced one woman with unilateral pain radiating from the lumbar region round to the pelvis. She had had an inflammatory mass removed from her abdomen and a subsequent nephrectomy without relief, and died suddenly after a profuse hæmorrhage from a spinal tumour. Cases of "curious pain" should always suggest spinal cord tumour.

Mr. WALTON said that the slower the course the better the prognosis, as the ultimate results depended less on the presence of a tumour than on the damage it had done, which was proportional to the rapidity of its growth. All cases should be operated upon at once. He agreed with Mr. Armour's technique. What operative risks there were were the accidental risks of all operations.

TREATMENT OF GANGRENE.

Mr. SAMPSON HANDLEY (London), in opening the discussion, said he proposed to confine his remarks to more recent methods of vasomotor surgery in relation to gangrene, and gave a brief history of the subject. He described Leriche's method of performing periarterial sympathectomy and stated that this surgeon had had successes in various conditions, but he did not perform his operation for gangrene. According to Prof. Leriche, after sympathectomy there is a local contraction of the artery, and for some hours pulsation is feeble and the limb is colder than its fellow. This is followed by elevation of the temperature of the limb and of the arterial pressure, and by increased amplitude of the pulse for from three to four weeks.

The speaker then drew attention to his method of alcohol injection, which he believed was a definite advance on Leriche's operation, and claimed that in certain cases it will avert threatened gangrene, or arrest the spread of senile gangrene already present, and so obviate amputation. The technique used is to expose the femoral artery in Hunter's canal for 1 to 2 in. With the finest possible hypodermic needle 2 to 3 minims of alcohol are injected at four points spaced round the artery, the needle being inserted obliquely and nearly parallel to the vessel. When the injection is complete a whitish band about ½ in. wide should be seen round the artery, but no constriction takes place. The effect of alcohol injection is that the foot in successful cases becomes warmer almost at once and the vasodilatation may last for a year or more, whereas it is stated to pass off in a few weeks after Leriche's operation. Mr. Handley mentioned some criticisms of the method and stressed the difficulty of making a proper selection of cases at present. In regard to indications, he would advise it strongly in cases of threatened or incipient gangrene of a lower limb, but would prefer to employ it in the prodromal stage. He considered it useless in Buerger's disease and of doubtful value in Raynaud's disease. Finally, he claimed that alcohol injection was a distinct advance on Leriche's operation, and appealed to medical men when first consulted for symptoms of arterial dystrophy to allow vasomotor surgery a fair field in its attempts to avert the onset of gangrene and the loss of a limb.

Mr. PHILIP TURNER (London) said he would confine himself to the clinical aspects of periarterial sympathectomy, which he had performed eight times, twice by operation and six times by alcohol injection. Of these, three were very striking successes which he narrated, three were temporarily improved, and two, whose general condition was very bad, died. Mr. Turner pointed out that following sympathectomy the following clinical effects were seen whatever their cause—namely, increased warmth of the foot, relief of pain, disappearance of swelling, rapid formation of a line of demarcation, and improvement in general condition. Mr. Turner said this operation was a valuable addition to amputation, which might be avoided in 25 per cent. of cases and delayed in 50 per cent., and in his opinion it is particularly indicated in early cases of senile gangrene and should be carried out as soon as the diagnosis is made.

Mr. E. G. SLESINGER (London) could not agree that sympathectomy acted by dividing the vasoconstrictor fibres; all modern evidence, he said, was against this. He suggested that what were divided were the afferent sensory nerves of the arteries, and the effect of sympathectomy was due to breaking the reflex arc. He discussed arterial pain and compared the pain of angina pectoris and abdominis with that of incipient gangrene. In his experience the operation succeeded when there was reflex spasm in addition to organic narrowing. He could see no advantage in the method of alcohol injection over sympathectomy which he had performed 25 times with no mortality. Finally, he urged that sympathectomy should be tried in all painful cases of organic vascular disease, since it would relieve pain almost certainly and might, in addition, improve the circulation.

Mr. W. A. COCHRANE (Edinburgh) had treated cases of gangrene by exposing the main artery and rubbing it with gauze, and had had successes. He considered it of no value in endarteritis obliterans, but had found temporary benefit in varicose ulcers.

Sir WILLIAM WHEELER (Dublin) had no experience of alcohol injection. He related cases of thrombo-angiitis obliterans in which he had performed sympathectomy with no benefit and with no relief of pain, and he stressed the importance of removing the whole sheath.

Mr. R. StL. BROCKMAN (Sheffield) put in a strong plea for alcohol injection on the ground of simplicity which brought it within the compass of every surgeon. He considered it of value as a preliminary to amputation.

Mr. HANDLEY, in replying, mentioned the possible danger of absorption of toxic materials from the dead gangrenous part as the result of vasodilatation after operation.

FALLACIES OF X RAYS IN ABDOMINAL DIAGNOSIS.

At a discussion held jointly with the Section of Radiology, Mr. H. J. PATERSON (London) began by pointing out that medicine, being essentially an art, laboratory methods can never replace clinical observation. The chief fallacies as regards surgery might be grouped as: (1) those incidental to X rays; (2) those due to errors of technique; (3) those of misdirection; (4) those of interpretation. Under (1) the speaker said that X rays exaggerated stasis and a better method of estimating this was the charcoal method; a further fallacy under this head was spasm. Duodenal ulcers were seldom shown by X rays, but often inferred when not present, and whether gastric ulcers were shown depended on their size and depth. Under fallacies of technique were instanced the need for exposures in different positions, and the importance of having the stomach well filled with barium. Fallacies of misdirection consist of diverting the attention to some abnormality of less serious import than the main disease. The last group of fallacies of interpretation were numerous and cases were mentioned of error in connexion with gall-stones, ureteric calculi, appendicitis, gastric ulcer, adhesions, &c. Mr. Paterson said an insidious fallacy was the claim that healing of a gastric ulcer could be shown by X rays. Ulcers are stated to heal in a few weeks after alkali treatment, but is the evidence good enough considering the intermittent nature of the disorder? Finally, the opener said he did not question the utility but the infallibility of X ray diagnosis.

Dr. F. HERNAMAN-JOHNSON (London) stressed the advantage of X rays over charcoal in localising stasis of the bowel. In regard to spasm he would hold that spasm persisting after full doses of belladonna shows some lesion in the alimentary tract. Failure to find organic lesions does not prove their non-existence, and a negative X ray can only exclude gross deformity. He objected to including fallacies of misdirection, as it is important to demonstrate any definite lesion. Fallacies of interpretation must always remain and no radiologist could differentiate on X ray evidence only between an inflammatory lump and carcinoma. It is important for radiologists to indicate which of their deductions depend on X ray findings and which on examination and history. The speaker pointed out the importance of not calling an appendix normal because X ray examination does not incriminate it, and stated that a pelvic cæcum which does not rise on a barium enema and which contains residue after 24 hours often means appendicitis.

Dr. A. F. HURST (London) said the diagnosis of gastric and duodenal ulcer depended largely on the skill of the radiologist and in experienced hands should be right in 90 per cent. of cases. He would never diagnose gastric or duodenal ulcer without X ray evidence and the same applied to carcinoma. In his opinion, if there was no obstruction, all gastric ulcers would heal if treated medically, provided treatment was sufficiently long and thorough, and their healing could be shown by X rays. Dr. Hurst mentioned the fallacy by which a not uncommon diverticulum in the region of the cardia is mistaken for ulcer.

Mr. W. MCADAM ECCLES (London) stressed the importance of a complete radiological examination, and mentioned cases where incomplete examination had led to unnecessary removal of the appendix.

Prof. A. FULLERTON (Belfast), after pointing out the necessity of piecing together the evidence of various investigators in order to make a diagnosis, discussed the value of stereoscopic X rays in differentiating phleboliths and calcareous glands from urinary calculi.

Sir WILLIAM WHEELER appealed to radiologists to follow-up operations performed on cases they had seen, and said it was important not to give too definite a negative report lest further observation of the case might be discouraged. Personally, he thought there was no such thing as medical treatment for chronic gastric ulcer.

Mr. RENDLE SHORT (Bristol) spoke of the value of coöperation between radiologist and surgeon and of the difficulty of *proving a negative*. In his experience, if the clinical diagnosis and the X ray diagnosis differed, the X ray diagnosis was more often the correct one.

Dr. T. I. CANDY (Newport) said that cases were often sent for barium meal examination too casually and without adequate notes. He asked that radiologists should be given proper data and that it should be remembered that they were often the only units of the team whose opinion was committed to paper and could be held against them.

The Chairman, Prof. A. W. SHEEN (Cardiff), spoke of the effectual cooperation that existed in his clinic, and said that negative X ray findings were often as important as positive ones.

Dr. O. LEWELLIN RHYS (Cardiff) likened the radiographer of some years ago to the race-course tipster who had to name the winner before the race, and was abused if he failed to do so. Nowadays, the surgeon must bear his share of responsibility for a preoperative diagnosis.

SECTION OF PATHOLOGY AND BACTERIOLOGY.

Sir THOMAS HOUSTON *took the chair at a discussion* on the

BACTERIAL FLORA OF THE INTESTINE IN HEALTH AND CHRONIC DISEASE

which was opened by Prof. J. CRUICKSHANK (Aberdeen), who surveyed the bacterial contents of the newly born and traced the changes that occur as age advances. He pointed out that the meconium is sterile, but organisms appear in small numbers in the first 24 hours after birth. During the first few days the organisms most frequently found are the *Staph. albus*, *Strept. fæcalis*, and members of the *B. coli* group. In the first sample of the meconium free fæces an organism of the *B. bifidus* type, appears. This latter organism increases in number and replaces other organisms to a large extent. If the child is breast fed, the *bifidus* type constitutes 95 *per cent.* of the organisms present. In artificially fed infants the predominant organisms are of coliform type. The fæces of breast-fed infants are distinctly acid in reaction, while those of artificially fed infants are alkaline or neutral. *B. bifidus* and organisms of the *acidophilus* type can survive exposure to highly acid fluids, which destroy coliform organisms. Thus the bacterial content of the intestine is related to the chemical reaction. Spore-bearing organisms are absent from the suckling's stool for the same reason. When breast-feeding is over opportunity is offered for the invasion of the alimentary canal by many organisms. The intestinal organisms have been grouped into two types, proteolytic and saccharolytic. Experimentally it has been found that a high carbohydrate diet gives a flora rich in *bifidus* and *acidophilus*, whereas a high protein diet gives a predominance of coliform organisms and spore bearers. Lactose appears to be the determining factor in the production of the saccharolytic type of flora. In 1915 Torrey reported favourably upon the use of lactose in typhoid fever, a most marked change occurring in the bacterial flora. The same treatment has been applied to conditions of intestinal origin in children associated with lassitude and anorexia with diarrhœa or constipation, in which there is proteolytic intestinal flora. A quicker transformation of the flora is achieved by combining lactose diets with cultures of *acidophilus* organisms. Prof. Cruickshank attributed the action of the sugar to its being attacked by *B. coli* and *B. welchii*, the various acid substances produced offering a suitable pabulum for the growth of *B. acidophilus*. This is suggested by the fact that direct inoculation of fæces into milk gives abundant growth of *B. coli* and enterococci in the first few days, but at a later date vigorous growth of *B. acidophilus* occurs. Sugars other than lactose have been tried but the above results have not been obtained. Starchy foods, however, tend to change the flora. The administration of animal proteins, on the other hand, produces a marked proteolytic or putrefactive flora. The speaker emphasised that to change the type of bacteria to the acid variety large quantities of lactose must be used, together with an *acidophilus* culture capable of surviving in the intestine. He further declared that the types of intestinal flora are most probably the result of abnormal intestinal conditions and not the cause of them. Dealing with the subject of auto-intoxication, he said that nothing had emerged from chemical or bacterial research in recent years to support the view that harmful substances are elaborated by bacteria in the intestine and then absorbed. It had been shown that a closed-off loop of intestine may contain very toxic material, but this is incapable of deleterious effects until the intestinal mucosa is grossly damaged. Experimentally produced intestinal obstruction in dogs tended to show that the resulting toxæmia is not so much due to bacterial disintegration above the obstruction as to mechanical disturbances below. In chronic ulceration there is frequently no evidence of intestinal toxæmia in many cases, although it might be expected that absorption of toxic substances would take place at the site of damage of the mucosa. Many workers have held that intestinal mucus is an important defence against the invasion of organisms. Absence of vitamin A from the diet has been shown to produce changes in the mucous glands, and it is believed that these changes permit the entry of organisms normally held at bay. These views have been confirmed by further work in which animals have been fed on a diet deficient in vitamin A and subsequently found to be much less resistant to pathogenic organisms administered by the alimentary canal than other animals on a normal diet. It has been also shown that there is a relationship between the reaction of the intestinal contents and the occurrence of rickets, in this latter pathological condition the cæcal contents being alkaline while administration of cod-liver oil results in a change to an acid reaction. Deficiency in vitamin B is also associated with alkalinity of the cæcal contents. In considering the possible relationship of pernicious anæmia and intestinal toxæmia, it was pointed out that such relationship had not been proved. *B. welchii*, one of the organisms held responsible for the condition, is present in normal stools and no increase in pathogenicity or hæmolytic power has been found in pernicious anæmia. Further, bacterial toxins similar to that of *welchii* may be administered by the mouth without producing specific symptoms. Prof. Cruickshank strongly emphasised the importance of realising that an enormous variety of organisms can be cultured from normal fæces by various bacteriological methods, and he deplored the too often labelling of organisms as pathogenic with immediate recourse to the use of vaccines. Many of the organisms occurring in the intestine are ingested in the food and dust and are passively carried by the intestinal contents. Others find conditions suitable for multiplication. Before accepting an organism found in the stool as the causative agent even in acute intestinal disorders, much evidence other than its presence in considerable numbers, or that it shows pathogenic properties on injection into animals, must be presented. The organisms in the human intestine were compared with those occurring in the soil, the flora in each case being determined by the nature of the available food material. If the intestinal contents could be more frequently regarded as material which is outside of the tissues, and separated from these by a mucous membrane which is endowed with peculiarly selective absorptive powers, there would be less tendency to regard the bacterial flora of the intestine or its individual members as concerned in the causation of many chronic conditions in the human subject.

Discussion.

Sir THOMAS HORDER supported Prof. Cruickshank's contentions and said he was glad to receive academic support to his own beliefs on the subject. The standards at present used as criteria of pathogenicity of intestinal organisms are unsatisfactory. Further, there is no standard technique, with the result that clinicians are at a loss to understand the varying bacteriological reports on the same sample of material submitted to a variety of workers.

Prof. J. H. DIBLE (Cardiff) described a large series of investigations of intestinal organisms during the period of the war. In the first group of this series Morgan's No. 1 bacillus was extremely rare. There were no cases of dysentery in this group. In successive groups dysentery became a frequent occurrence and Morgan's No. 1 became proportionately more frequent. The criteria on which the diagnosis of hæmolytic streptococci is based was also carefully considered. Some methods show a large percentage of these organisms in the fæces in certain cases, but a more detailed and extended investigation throws doubt on the findings recorded. Prof. Dible also pointed out the extreme difficulty of determining the exact nature of a normal intestinal flora.

Dr. A. F. S. SLADDEN (Swansea) spoke from the point of view of a routine bacteriologist. He emphasised the need for clarity on this subject. Regarding technique, he believed that material from the mucosa rather than mixed fæces should be used in bacteriological investigations. Direct examination of stools for micro-organisms he considered of doubtful use. A new method of investigation is required, and such a method must be short to be of value to the clinical bacteriologist.

Dr. L. P. GARROD (London) had carried out a series of careful investigations in an attempt to establish what fraction of the intestinal bacteria in health and disease is composed of streptococci. He was able to show that a low carbohydrate diet was associated with a diminished number of streptococci. He was unable to show that the bile in the intestine had any effect on these organisms, neither did the chemical reaction influence the relative numbers. In cases of pernicious anæmia, colitis, and chronic arthritis no definite increase of streptococci could be found. Dr. Garrod believed that estimation of the numbers of streptococci as an indication of pathogenicity is misleading.

Dr. A. P. CAWADIAS (London) dealt with the clinical aspect. He classified intestinal infection into extra-infection and auto-infection. The auto-infections may be of saccharolytic or proteolytic type. He had obtained good results by the use of vaccines. He said further that cases of auto-intoxication occurred with no symptoms of intestinal disturbance. He considered the possibility of mild anaphylaxis being the cause of these latter conditions should be given every consideration.

The CHAIRMAN expressed the opinion that the percentage of streptococci found in the stools depends on the cultural method used. The discussion had shown that no useful conclusions could be drawn from a bacteriological examination of the stools with present technique. It would be, however, difficult to convince clinicians on this point. An important point in favour of absorption of organisms from the intestine is the presence of intestinal organisms in remote parts of the body. The speaker had investigated several cases in which the enterococcus was believed to be the organism causative of lesions in urinary tract and nose. An organism had been isolated from stools in cases of ulcerative colitis by Burger and by Houston. This organism, believed to be the cause of the associated lesion, is said by the speaker to be of enterococcus type. He had also obtained good results from vaccines in cases of believed intestinal auto-intoxication of enterococcus type.

Reply.

Prof. CRUICKSHANK, in reply, said it is necessary to show that organisms or their toxins are absorbed before good results said to be obtained by vaccines can be claimed to be due to antibodies. If chemical substances are absorbed the formation of antibodies to combat them is unlikely. He expressed doubt on the benefits claimed from vaccine treatment. The possibility of anaphylaxis as a resultant of disturbed intestinal conditions was worthy of consideration.

SECTION OF ORTHOPÆDICS.

UNDER the presidency of Sir JOHN LYNN-THOMAS a discussion on

LOW BACKACHE AND SCIATICA

was opened by Mr. W. A. COCHRANE, who said that careful eliminative diagnosis left a large group which was essentially orthopædic, and which included the industrial lame backs. A painstaking and meticulous routine examination was of the utmost importance. Special attention must be paid to the anatomical type of the individual. The slender, tall and lanky, or small and delicate patient was unfit for heavy work and subject to functional breakdown of the back. The second point for consideration was the impairment of the normal balancing mechanism by bad posture. The lumbo-sacral joints in particular were overloaded in heavy people with prominent sagging abdomens, and the sacro-iliac joint was also exposed to static insult from flat-foot, short leg, or a hip affection. When X rays revealed no intrinsic lesion of the lumbo-sacro-iliac region the need for accurate diagnosis was acute. A negative X ray photograph did not warrant the assumption that there was nothing the matter with the patient, and careful reading of good stereoscopic radiograms often revealed a departure from normal in extrinsic lesions. In cases of alleged injury the symptoms were usually out of all proportion to the severity of the trauma. Compression fractures of the spine sometimes followed comparatively minor injuries, and were often overlooked. A lateral view often revealed a lesion that had been overlooked in the antero-posterior view. A complex and difficult problem was that of the relationship of anatomical variations of the fifth lumbar vertebra to backache and sciatica; was the association causal or casual? As Osgood said, the abnormality was to be regarded as potentially contributory, and there was an undoubted connexion between the presence of abnormality and the occurrence and persistence of symptoms.

The most difficult problem in cases of injury was the mental one. Malingerers, however, were not common. The workman was often genuinely deceived as to the true sequence of events, and, having little to show for his symptoms, was apt to exaggerate.

Differential diagnosis was always difficult, and definite intrinsic pathological lesions of bone and joint must first be eliminated. The chief points to be noted were the general build and attitude of the patient; the presence or absence of the normal lumbar curve, of listing or lateral deviation of the spine, of restricted and painful movements, of spasm or wasting of muscles, of swelling and points of tenderness, and the nerve function in the legs.

Clinical Classification.

Acute traumatic strain was a rupture of ligamentous and muscular fibres with all the phenomena of acute injury. A lesion in muscle caused pain when the muscle was thrown into action; a lesion of fibrous tissue when it was put upon the stretch; a lesion of bone or joint on all movements of the spine. The treatment was rest. A superadded infective focus might keep up the disability, as would also poor bodily mechanics and posture. While complete rest was advisable for a torn muscle or aponeurosis, a sprained joint should be made active as soon as possible.

General postural strain was a condition of general muscular fatigue and ligamentous strain. The patient complained of dull aching in the shoulders and low back, relieved by rest. There was usually poor posture and fatiguing occupation. Treatment was by rest, support, and postural re-education.

Lumbo-sacral strain showed itself by dull or acute pain indefinitely localised over the lower spine and hip, chiefly on one side, often accompanied by sciatica, and generally relieved by rest. Forward bending was limited by spasm of the hamstrings, and there was local tenderness on deep pressure and flexion of the hip with knee extended was limited. The treatment aimed at flattening the lumbar spine by rest, hot fomentations, and suitable exercises.

Sacro-iliac strain, in contrast to lumbo-sacral strain, usually affected the slender, visceroptotic type with poor posture. Sacro-iliac subluxation was rare, but sacro-iliac joint strain was common. There was referred pain along the first and second sacral nerves, and the tender spots were the inferior sacro-iliac ligament, the sacro-sciatic notch, and sometimes the trunk of the sciatic nerve. The diagnostic points had been well set out by M. N. Smith-Petersen.[1] The treatment was by rest and support, followed by heat, massage, and education to flatten the lumbar spine and undo the forward tilting of the pelvis. Mild cases were relieved by strapping, but usually a light brace and well-made corsets were required for a time. In more resistant cases the joint must be manipulated or ankylosed.

Combined pelvic joint strain.—Clinical features referable to both joints might be found together. An enlarged fifth lumbar transverse process causing pain usually responded to prolonged immobilisation, and support and operation was often successful. A better plan was to ankylose the lumbo-sacral region.

The Pathogenesis of Idiopathic Sciatica.

A mass of reliable evidence was now available to prove that many cases of sciatica could be traced to an anatomical lesion or abnormality in the lumbo-sacral region of the spine. There was localised pain and tenderness on deep pressure, sciatic scoliosis and pain referred along the sciatic nerve, which was not usually tender. Painful semi-sacralisation of the fifth lumbar vertebra was now a well-recognised entity. Abnormalities of the facets were not unusual, and poor posture still further reduced the size of the small foramen, already filled with the large fifth lumbar nerve. Treatment was by prolonged recumbency and immobilisation of the spine, combined with hyperæmia.

Mr. P. J. VERRALL said that in the backache of pregnancy less and less could be ascribed to uterine misplacements, though intrapelvic trouble might lead to pain referred along the third sacral nerve, much more superficial than the pain of sacro-iliac strain. A large factor in the production of this pain was the chronically over-distended rectum. The commonest causes of backache were: (1) Chronic overstrain of the erector spinæ or abdominal muscles. The muscles tried to maintain tone and then gave way, causing low backache in the case of the erector spinæ and lordosis in the case of the abdominal muscles. (2) Fixed flexed hip, due to irritation of the psoas by a chronically inflamed appendix or overloaded sigmoid. In these cases there was always tenderness in one iliac fossa. (3) Subinvolution of the sacro-iliac joints. Relaxation of these joints occurred during pregnancy and the menstrual periods. A subsequent involution similar to that of the uterus should occur. If this failed, backache was the result.

The typical deep tenderness over the sacro-iliac joints was always found, and the other sacro-iliac tests were positive.

In sciatica following pregnancy the question of how much was due to toxæmia and how much to trauma had to be decided. There was no doubt that both fourth and fifth nerves might be injured, as in maternal obstetric paralysis.

Mr. D. MCCRAE AITKEN said that with the present school medical inspection two most fruitful sources of backache—round shoulder and hollow back—were fast disappearing. Crush injuries were much commoner in young children than was generally believed, as they occurred when the bones were still largely cartilaginous. The long back was ill-supported by the erector spinæ and the importance of the oblique and quadratus lumborum muscles was often overlooked. Much of the pain was probably due to quadratus lumborum. "Where you have tension, there you have pain." It was at the origin of the muscles from bone that the strain occurred, and when the muscles gave way the strain fell on the ligaments, causing swelling and pain. In treatment, consideration must be paid to the existence of a toxic element, especially large bowel absorption. In "ricked back" a strip of muscle often got kinked over a bony process producing an elongated swelling. Manipulation would release this strip and give a dramatic cure.

Mr. WHITCHURCH HOWELL agreed that the efficient treatment of round shoulders, hollow back, and scoliosis would go a long way in preventing backache. He discussed the diagnosis of backache, which should be grouped under the headings of: (1) lumbago, (2) anatomical abnormalities, (3) trauma, (4) sciatica.

---

[1] Jour. Bone and Joint Surg., 1926, viii., 118.

The latter should be subdivided into true and false (due to pelvic lesions, arthritis of hip, &c.).

Mr. ROCYN JONES said that cases of backache might be divided into two groups—the traumatic and the postural (including the industrial lame backs). Both groups were complicated by infection. Difficulty in diagnosis arose between lumbo-sacral and sacro-iliac lesions. In lumbo-sacral lesions the pain was in the mid-line, there was rigidity of the lumbar spinæ, and the leg-raising test gave equal results on both sides. In sacro-iliac lesions the pain was below the posterior superior iliac spine, the lumbar spine was not rigid, and the leg-raising test caused earlier pain in the affected side. Stereoscopic X rays should always be taken. He stressed the difficulty in the differential diagnosis between sacro-iliac strain and early tuberculous disease. Until bony changes appeared in the latter differentiation was impossible. As regards treatment he agreed entirely with Mr. Cochrane.

Discussion.

Mr. ALAN TODD spoke of the causation of lordosis with backache in young men. Paralysis of the abdominal muscles due to muscular dystrophies, or anterior poliomyelitis and visceroptosis were the causes of several recent cases he had treated. Adequate supports by belts relieved these conditions, but in nonparalytic cases must be regarded as a temporary measure only. He emphasised the need for more orthopædically trained masseuses. This would only be obtained by making orthopædic surgery an essential part of medical training.

Dr. R. MANWARING-WHITE said that practitioners were to a large extent responsible for chronic backache, as the initial injury was often trivial and was then overlooked. The importance of toxæmias must not be underestimated.

Dr. W. A. MARRIS maintained that many cases were due to general ill-health. They were, in fact, "tired backs."

Dr. E. SOLLY complained that many patients were sent to him with a diagnosis of sciatica who were really suffering from an intrapelvic growth, frequently malignant, and not even in an early stage. These should be eliminated by careful rectal examination. Joint disease also often led to an error in diagnosis.

Mr. COCHRANE, in reply, said that he hoped to work on the lines indicated by Mr. Verrall—i.e., the relation of constipation, visceral tone, and other intra-abdominal lesions to backache. He pointed out the difference in the postural and kinetic use of muscles and the importance of physical training. He emphasised the importance of careful rectal examination of all cases.

VOLKMANN'S ISCHÆMIC CONTRACTURE.

Sir ROBERT JONES said that few cases were reported, because there was an idea that this condition conveyed some slur on the treatment; it ought, therefore, to be laid down most emphatically and intelligibly that ischæmic paralysis arose without any carelessness on the part of the practitioner. The essential pathological changes were degeneration of muscle and an increase of connective tissue in their substance, often with absence of sarcolemma nuclei. There was a round-celled infiltration and absence of transverse striation. The process was one of absorption and replacement of dead muscular tissue. The deformity was found mainly in children under 14 after injury to the elbow, and was due to pressure. About 80 per cent. of cases were associated with fracture. In a typical case the wrist-joint was palmar flexed, the carpometacarpal bones were dorsiflexed, the interphalangeals flexed, the hand pronated, and the elbow flexed. As a rule sensation and electric reactions were normal and the fingers could be straightened on flexing the wrist. The skin was blue, cold, and sometimes blistered and scarred. The muscles wasted rapidly and became hard and ropy; if the nerves were sufficiently involved conduction might be partially or wholly lost. Symptoms might appear a few hours after injury, and the damage was often completed in 48 hours. The contracture was preceded by numbness, swelling, muscular rigidity, and sometimes intense pain. If untreated the deformity increased, from contraction of the fibrous muscle and the disproportional growth of bone.

Mild Ischæmia.

Sometimes children were unable, months or years after elbow injuries, fully to flex their fingers. These cases suggested that a slight degree of ischæmia might be quite common, just as blue, swollen fingers might recover after the relief of pressure from splints. Brooks's experiments supported the contention that the hæmatoma within the antecubital fossa might produce venous block quite apart from bony displacement, splinting, or bandaging. Jepson had failed to produce anything but very temporary deformity by the application of splints, casts, and bandages to dogs. A persistent lesion had only been procured by application of an Esmarch bandage after incision and ligation of the femoral vein. If the wound were well drained the contracture could be prevented. The chief factor, therefore, in Volkmann's contracture was a direct pressure from within or without, causing acute obstruction to venous flow. Inflammatory products added to the pressure. J. J. Thomas had found nerve involvement in 60 per cent. of his series.

Prophylaxis.

Under no circumstances, therefore, should an elbow be tightly bandaged. The fracture should be reduced completely and at once. The backward displacement of the humerus must be corrected before putting the arm up in flexion; a sharp projecting upper fragment often added to the internal venous obstruction. Reduction was not easy if postponed for days. The arm should not be bandaged to the forearm nor the elbow to the side, but intelligent flexion was perfectly safe. If a surgeon could not reduce the fracture by manipulation he had better operate than leave it. All circular compression and splints should be avoided, especially if there were much swelling. All cases should be critically watched for the first few days. If great pain, stiffening, swelling, lividity of the fingers, or loss of voluntary movements appeared, the arm should be released from all compression and elevated. The methods of subcutaneous division on the antero-ulnar side of the forearm and of multiple incisions to evacuate the subfascial hæmatoma were worthy of further trial.

The prognosis was always grave, and worst of all when the nerve damage was excessive, when the obstruction to circulation remained pronounced, and when there was only mass movement in the fingers, and the wrist was fully flexed with the forearm fixed in extreme pronation. Treatment of the established condition was mechanical or operative, the aim being to keep the forearm supinated. The former line of treatment consisted in gradually extending first the fingers, then the metacarpophalangeal joints, then the wrist. Physiotherapy had an assured position and should include radiant heat, contrast bathing, oil stupes, gentle massage, and electrical stimulation of the muscles. When a nerve was divided operation was imperative, and the after-care was most important in cases of tenoplasty. Myotomy and tenotomy were not to be recommended. Free excision of the elbow-joint might be indicated when there was contraction of tendons and fixation of the forearm in pronation.

Practitioners must insist on an X ray photograph or a refusal of it in writing, and should warn the patient of the possible serious results of an elbow injury: Volkmann's contracture and myositis ossificans. Further, they should join a medical defence union, for the law might be invoked whatever they did.

Mr. W. ROWLEY BRISTOW pointed out that ischæmic paralysis meant death of muscles, therefore both faradic and galvanic reactions were lost; in the milder cases they would be normal. Nerve suture was worth while, even if the muscles were beyond recovery, as it restored gross sensibility. He emphasised the fact that the position for setting up fractures of the elbow was not " full " or " acute " flexion, but partial flexion across the chest.

Why the Forearm Only?

Mr. D. **McCrae Aitken** remarked that Sir Robert Jones never under any circumstances " stretched " a case " on splints "; he was most careful not to put a limb up in any tension. Volkmann's contracture was one thing—primarily a congestion, a deposition of lymph, and an organisation of fibrous tissue throughout the muscle, producing strangulation; nerve injury was another thing which might occur at the same time and ought to be dealt with at once. He suggested that the reason why the forearm was particularly affected was that its muscles were extremely highly organised with quick and fine reflex adjustments to each other, and therefore highly vulnerable in their function. He quoted a case which suggested that something depended upon re-education of the coördinating movements, and so upon the development of muscles which might not otherwise be restored to function.

Mr. H. **Platt** put forward an anatomical explanation of the susceptibility of the forearm muscles, which arose from a small origin, and swept up obliquely, enclosed in a very tight compartment with a roof of unyielding fascia. Between internal and external condylar groups the biceps tendon was interposed. In this " box " it was easy to get pressure obstructing the venous return along the venæ comites of the ulnar recurrent arteries. The median nerve, passing between the heads of pronator radii teres, inevitably get strangled as the fibrous tissue contracted. A great advantage of operation was that the nerve could be freed and the muscles stripped off the epicondyle, thus giving a very good start.

Mr. D. S. **Middleton** recorded some investigations into Volkmann's myopathy, particularly as it affected the sternomastoid in congenital wryneck. Scar tissue only occurred as a result of muscular death when the venous drainage was obstructed so that the products of autolysis could not be removed by the usual channels. They thus formed an irritating foreign body which was dealt with by the usual process of revascularisation and scar formation. Three or four days after venous ligature all the muscles were invariably found cyanosed, swollen, and necrotic, but a few months later some of them would be found to have recovered. A striking thrombosis occurred in the venous tree and was organised. Probably the temporary interference with venous return produced by ligature was not enough to cause fibrosis, but was converted into a secondary permanent interference by thrombosis.

Anatomically there was little connexion between the deep and superficial venous systems of the forearms below the bend of the elbow, and the venæ comites of the ulnar arteries were much larger than those of the radial. At the bend of the elbow there was a venous plexus that could be covered with a sixpence, and pressure on this meant obstruction to the venous return from almost the whole forearm. The profunda vein entered over the firm fibrous arch connecting the radial with the humero-ulnar origin of the flexor sublimis digitorum. A hæmatoma would force the veins down on to this edge and produce obstruction. Drainage operations therefore seemed reasonable. Mr. Middleton mentioned that of José Jorges, of Buenos Aires, who freely divided all the aponeurotic sheaths in a zigzag fashion to allow expansion and free drainage. If thrombosis had started, however, operation could not be expected to give complete recovery. Mr. Middleton concluded that Volkmann's ischæmic contracture resulted from interference with the venous return by a hæmatoma in a definite, localised spot in the antecubital fossa. It depended therefore on causes associated with the initial injury, and methods of treatment—or the absence of treatment—played a minor part, if any, in its production. It was not yet possible to say which cases would develop this complication, and it was doubtful whether that knowledge would materially assist its prevention.

Discussion.

Mr. **Todd** said that in view of the gross injustice which had recently been done to a member of the profession it was the duty of everyone to record cases of ischæmic paralysis occurring in the absence of any kind of splinting, strapping, or bandaging. He described two such cases, one an extremely bad and hopeless one following a fracture which had lain loose on a pillow without treatment, and the other, less grave, following dislocation of the elbow which had been reduced and sent away in a sling. He pointed out that it was never necessary to use an anterior splint or occlusive plasters for any fracture of the forearm; adequate posterior splintage gave perfect reduction. The teaching that a pad under the anterior splint helped to separate the bones of the forearm was false and pernicious.

Mr. **Howell** recorded some personal experiences, and pointed out that Volkmann's contracture was not a common thing, but that every injury of the elbow-joint ought to bé regarded as a potential ischæmic paralysis. The treatment was to incise the hæmatoma, and to follow in detail Sir Robert Jones's method, by which independent joints were splinted with independent splints by an orthopædic masseuse. It was not possible to get more than a ¾-inch gap at operation without risk to the arterial supply. He described a modification of the collar-and-cuff method which ensured supination from the start.

Mr. P. J. **Verrall** did not agree that ¾ inch was the maximum gap; the muscles could be stripped right across the interosseous membrane without any injury to vessels or nerves, provided always that this operation was never regarded as anything but an adjunct to Sir Robert Jones's stretching method.

Mr. **Rocyn Jones** agreed that the condition might come on without any splinting, and that this fact was one of the most important things to bring home to the public. He was glad to hear stress laid on the value of drainage in cases where there was œdema.

Sir **Robert Jones**, in reply, agreed that " acute flexion " was quite the wrong term for the correct position of fractured elbows, and that force should never be used in stretching the fibrous tissue—it was a real coaxing.

EXHIBITION OF DRUGS, SURGICAL INSTRUMENTS, FOODS, AND APPLIANCES.

The usual trade exhibition was opened in the Drill Hall, Cardiff, on July 24th. A brief notice of the more important exhibits is given below, and will be concluded in the next issue of The Lancet.

Drugs and Pharmaceutical Preparations.

1. *General Drug Exhibits.*

[46] Allen and Hanburys, Ltd. (Bethnal Green, E. 2), drew attention to the fact that their " Allenburys " infant foods now have added to them a proportion of synthetic vitamin D, ergosterol, so that they fully protect against rickets. Among the " Azoule " brand sterile hypodermic ampoules are sodium salicylate and urethane preparations for the treatment of varicose veins. Liver extract for pernicious anæmia is prepared in powder, tablets, and capsules. " Charkaolin " is a new preparation for fermentative intestinal infections, combining the absorbent properties of vegetable charcoal with the toxin-adsorbing qualities of " Osmo " kaolin. A new laxative is " Byno Chrismol " with a cold-water extract of senna pods. " Iodolysin " is a fibrolytic agent for rheumatoid arthritis and allied conditions.—[60] Bayer Products, Ltd. (19, St. Dunstan's-hill, E.C. 3), showed a series of their well-known preparations, such as " Adalin," " Luminal," and " Plasmo-

The latter should be subdivided into true and false (due to pelvic lesions, arthritis of hip, &c.).

Mr. ROCYN JONES said that cases of backache might be divided into two groups—the traumatic and the postural (including the industrial lame backs). Both groups were complicated by infection. Difficulty in diagnosis arose between lumbo-sacral and sacro-iliac lesions. In lumbo-sacral lesions the pain was in the mid-line, there was rigidity of the lumbar spinæ, and the leg-raising test gave equal results on both sides. In sacro-iliac lesions the pain was below the posterior superior iliac spine, the lumbar spine was not rigid, and the leg-raising test caused earlier pain in the affected side. Stereoscopic X rays should always be taken. He stressed the difficulty in the differential diagnosis between sacro-iliac strain and early tuberculous disease. Until bony changes appeared in the latter differentiation was impossible. As regards treatment he agreed entirely with Mr. Cochrane.

Discussion.

Mr. ALAN TODD spoke of the causation of lordosis with backache in young men. Paralysis of the abdominal muscles due to muscular dystrophies, or anterior poliomyelitis and visceroptosis were the causes of several recent cases he had treated. Adequate supports by belts relieved these conditions, but in nonparalytic cases must be regarded as a temporary measure only. He emphasised the need for more orthopædically trained masseuses. This would only be obtained by making orthopædic surgery an essential part of medical training.

Dr. R. MANWARING-WHITE said that practitioners were to a large extent responsible for chronic backache, as the initial injury was often trivial and was then overlooked. The importance of toxæmias must not be underestimated.

Dr. W. A. MARRIS maintained that many cases were due to general ill-health. They were, in fact, "tired backs."

Dr. E. SOLLY complained that many patients were sent to him with a diagnosis of sciatica who were really suffering from an intrapelvic growth, frequently malignant, and not even in an early stage. These should be eliminated by careful rectal examination. Joint disease also often led to an error in diagnosis.

Mr. COCHRANE, in reply, said that he hoped to work on the lines indicated by Mr. Verrall—i.e., the relation of constipation, visceral tone, and other intra-abdominal lesions to backache. He pointed out the difference in the postural and kinetic use of muscles and the importance of physical training. He emphasised the importance of careful rectal examination of all cases.

VOLKMANN'S ISCHÆMIC CONTRACTURE.

Sir ROBERT JONES said that few cases were reported, because there was an idea that this condition conveyed some slur on the treatment; it ought, therefore, to be laid down most emphatically and intelligibly that ischæmic paralysis arose without any carelessness on the part of the practitioner. The essential pathological changes were degeneration of muscle and an increase of connective tissue in their substance, often with absence of sarcolemma nuclei. There was a round-celled infiltration and absence of transverse striation. The process was one of absorption and replacement of dead muscular tissue. The deformity was found mainly in children under 14 after injury to the elbow, and was due to pressure. About 80 per cent. of cases were associated with fracture. In a typical case the wrist-joint was palmar flexed, the carpometacarpal bones were dorsiflexed, the interphalangeals flexed, the hand pronated, and the elbow flexed. As a rule sensation and electric reactions were normal and the fingers could be straightened on flexing the wrist. The skin was blue, cold, and sometimes blistered and scarred. The muscles wasted rapidly and became hard and ropy; if the nerves were sufficiently involved conduction might be partially or wholly lost. Symptoms might appear a few hours after injury, and the damage was often completed in 48 hours. The contracture was preceded by numbness, swelling, muscular rigidity, and sometimes intense pain. If untreated the deformity increased, from contraction of the fibrous muscle and the disproportional growth of bone.

Mild Ischæmia.

Sometimes children were unable, months or years after elbow injuries, fully to flex their fingers. These cases suggested that a slight degree of ischæmia might be quite common, just as blue, swollen fingers might recover after the relief of pressure from splints. Brooks's experiments supported the contention that the hæmatoma within the antecubital fossa might produce venous block quite apart from bony displacement, splinting, or bandaging. Jepson had failed to produce anything but very temporary deformity by the application of splints, casts, and bandages to dogs. A persistent lesion had only been procured by application of an Esmarch bandage after incision and ligation of the femoral vein. If the wound were well drained the contracture could be prevented. The chief factor, therefore, in Volkmann's contracture was a direct pressure from within or without, causing acute obstruction to venous flow. Inflammatory products added to the pressure. J. J. Thomas had found nerve involvement in 60 per cent. of his series.

Prophylaxis.

Under no circumstances, therefore, should an elbow be tightly bandaged. The fracture should be reduced completely and at once. The backward displacement of the humerus must be corrected before putting the arm up in flexion; a sharp projecting upper fragment often added to the internal venous obstruction. Reduction was not easy if postponed for days. The arm should not be bandaged to the forearm nor the elbow to the side, but intelligent flexion was perfectly safe. If a surgeon could not reduce the fracture by manipulation he had better operate than leave it. All circular compression and splints should be avoided, especially if there were much swelling. All cases should be critically watched for the first few days. If great pain, stiffening, swelling, lividity of the fingers, or loss of voluntary movements appeared, the arm should be released from all compression and elevated. The methods of subcutaneous division on the antero-ulnar side of the forearm and of multiple incisions to evacuate the subfascial hæmatoma were worthy of further trial.

The prognosis was always grave, and worst of all when the nerve damage was excessive, when the obstruction to circulation remained pronounced, and when there was only mass movement in the fingers, and the wrist was fully flexed with the forearm fixed in extreme pronation. Treatment of the established condition was mechanical or operative, the aim being to keep the forearm supinated. The former line of treatment consisted in gradually extending first the fingers, then the metacarpophalangeal joints, then the wrist. Physiotherapy had an assured position and should include radiant heat, contrast bathing, oil stupes, gentle massage, and electrical stimulation of the muscles. When a nerve was divided operation was imperative, and the after-care was most important in cases of tenoplasty. Myotomy and tenotomy were not to be recommended. Free excision of the elbow-joint might be indicated when there was contraction of tendons and fixation of the forearm in pronation.

Further, they should join a medical defence union, for the law might be invoked whatever they did.

Mr. W. ROWLEY BRISTOW pointed out that ischæmic paralysis meant death of muscles, therefore both faradic and galvanic reactions were lost: in the milder cases they would be normal. Nerve suture was worth while, even if the muscles were beyond is now supplied in an improved atomiser with a cap.—[87] Behring Institute (Marburg-L., Germany, and W. Bredt, 41, Great Tower-street, E.C. 3) were showing again their delightfully convenient " Vacuum Venule " for the collection of blood samples, as well as " Yatren " in pills, powders, and solutions, and " Yatren-Casein " for protein shock therapy.—[49] Bristol-Myers Co. (112, Cheapside, E.C. 2) showed " Sal Hepatica," a saline regulator; " Ziratol," a non-toxic naphthaline antiseptic; and " Ipana," a tooth-paste containing Ziratol.—[6] G. W. Carnrick Co. (Brooks and Warburton, Ltd., 40–42, Lexington-street, W. 1) needed no introduction with their " Hormotone," " Trypsogen," " Secretogen," " Kinazyme," and other glandular compounds, but reminded the profession of the care with which these are prepared and standardised.—[67] Deshell Laboratories, Ltd. (Braydon-road, N. 16), argued once more the superiority of " Petrolagar " in its four forms: plain, unsweetened, alkaline, and with phenolphthalein. They laid stress on its value for cleansing, evacuating, or retention enemata, as it is miscible with anything, allays spasm, and holds the medicament in even dissemination on the mucous surface.—At Stand [26] Eno's Fruit Salt (Pomeroy-street, S.E. 14) held its own, and was a refreshing draught in the heat of the opening day.—[14] Ichthyol Co., Ltd. (18, Adam-street, W.C. 2), introduced " Albichthon," a colourless sulphur preparation from the raw material of ichthyol, an effective bactericide and clean to handle. Bristow's medicated " Ichthyol " toilet preparations were also on view.—[17] Jeyes' Sanitary Compounds Co. (London) showed a refined preparation of " Cyllin " for medical and surgical use, with a Rideal-Walker coefficient for *B. typhosus* of 24 to 26; as well as capsules for intestinal antisepsis, pastilles for the throat, soap powder, and dental and shaving cream.—[7] Kaylene, Ltd. (7, Mandeville-place, W. 1), this year emphasised the value of their colloidal silicate of alumina in infantile diarrhœa.—[71] Mond Staffordshire Refining Co., Ltd. (47, Victoria-street, S.W. 1), showed for the first time the " Monsol " products: pastilles, ointment, capsules, and anti-mosquito stick. The manufacturers maintain that Monsol is practically non-toxic and can be used intravenously, and that a 1/1000 solution is equivalent to 1/40 lysol at one-tenth of the price.—[84] The Saccharin Corporation, Ltd. (72, Oxford-street, W. 1), showed " Novocain " in powder, tablets, and solution, and " Glaucosan," a new and very strong myotic prepared by Dr. C. Hamburger, of Berlin, for the treatment of glaucoma.—[57] Scott and Turner, Ltd. (Gallowgate, Newcastle-upon-Tyne, and 211, Blackfriars-road, E.C. 4), dispensed " Andrews' Liver Salt " as in previous years with no sign of diminished activity.—[83] The Semprolin Co., Ltd. (18, Leather-lane, E.C. 1), prepare a wide range of emulsions of high viscosity paraffin, of which perhaps the most interesting are those containing respectively guaiacol and salol. " Carmex " is a soothing laxative mixture for infants. The firm are glad to find that the fact that their products are entirely British is being appreciated by the medical profession.

3. *Toilet Preparations.*

[33] Kolynos Inc. (Chenies-street, W.C. 1) and [31] Pepsodent Co. (42, Southwark Bridge-road, S.E. 1) presented their well-known dental creams. The former also showed a skin soap, liquid Kolynos for mouth-wash or gargle, and a denture powder, and the latter demonstrated the rotary cleansing action of their " Decoater " toothbrush.

FOOD AND DRINK.

[32] Benger's Food, Ltd. (Otter Works, Manchester), displayed the unique features of their food by a series of slides, and reminded the profession of the value of their peptonised beef and chicken jelly, extract of red marrow, and essence of rennet.—[41] Cadbury Bros., Ltd. (Bournville), emphasised the food value of milk chocolate, in every half-pound of which there are one and a half glasses of full cream milk.—[51] Maison Ackermann-Laurence (St. Hilaire-street, Florent, France) gave special prominence to an exhibit of sparkling Saumurs; their Brut Royal is free from tannic acid and excess of sugar and alcohol, and is rich in ethers. On the same stand Messrs. Francesco Cinzano, of Turin, exhibited Italian vermouth free from preservatives, wormwood, and wood spirit.—[1] Energen Foods Co., Ltd. (Willesden, N.W. 10), showed their wide range of foods, originally prepared for diabetic patients but now used in all metabolic disorders (see THE LANCET, 1927, ii., 1337). Their " Endobran " biscuits are prepared according to Dr. Poulton's formula, with a low carbohydrate and a high fat content.—The attendance at Stand No. 95, that of William Gaymer and Son, Ltd. (Attleborough and London), showed no sign of diminishing during the whole of the Exhibition. Their " Special Dry Still " cyder is recommended for diabetics and sufferers from gout. Sufferers from heat benefited from their " Medium Dry " and " Medium Sweet."—[30] Granose Foods, Ltd. (Watford), showed their crisp, steam-cooked biscuits made from whole wheat.—[93] H. A. G. Coffee Co., Ltd. (40, Theobalds-road, W.C. 1), dispensed refreshing cups of their coffee, and showed alarming specimens of the caffeine which had previously been extracted from the bean.—[80] Horlick's Malted Milk Co., Ltd. (Slough, Bucks), have added to their well-known milk preparation a pleasant malted milk toffee, and lay stress on the value of their shadow-food, consisting only of two ounces of malted milk, four ounces of barium sulphate, and water. A new mixer was also demonstrated.—[65] Ingram and Royle, Ltd. (45, Belvedere-road, S.E. 1), showed the many mineral waters for which they are agents, including Vichy-Célestins, Contrexeville, Carlsbad, and Hunyadi János.—[23] Keen, Robinson and Co., Ltd. (Carrow Works, Norwich), testified to the continued success of Almata as a food for infants, invalids, and nursing mothers, and have issued a new prescription for the preparation of their " Patent Barley," so that the mother is saved the trouble of preparing barley-water first. Robinson's Groats, Robinson's Oats, and Keen's Mustard Ointment need neither introduction nor recommendation.—[8] Montgomerie and Co., Ltd. (Ibrox, Glasgow), showed Berina Infant Foods and Berina Malted Milk invalid diet, as well as Bermaline Bread.—[70] Nestlé and Anglo-Swiss Condensed Milk Co. (6 and 8, Eastcheap, E.C. 3) emphasised the vitamin content, bacterial purity, and dietetic value of their full-cream milk and malted wheaten products.—[45] Oxo, Ltd. (Thames House, Queen-street-place, E.C. 4), had a new preparation, " Liveroid," for pernicious and general anæmia. To their " Oxoid " standardised endocrine preparations they have now added an ovarian and a parathyroid.—[61] Alexander Riddle and Co., Ltd. (Bancroft-road, E. 1), demonstrated practically the refreshing properties of Stower's Lime Juice, Lemon Squash, and Orange Squash.—[11] Vitalia, Ltd. (17A, Boniface-street, S.E. 1), showed that " Vitalia " Meat Juice with soda-water could be a refreshing drink as well as a valuable food.—[82] West Surrey Central Dairy Co., Ltd. (Guildford), have added to their well-known " Cow and Gate " infant food two new preparations: " Brestol," a humanised cream of standardised fat, protein and vitamin content, and " Lacidac," an acid milk powder with a hydrogen-ion concentration when reconstituted of pH 4·6.

SURGICAL INSTRUMENTS.

[46] and [63] Messrs. Allen and Hanburys, Ltd. (48, Wigmore-street, W. 1), called *especial* attention to their improved " St. Bartholomew's Hospital " pattern operation table, with new patent self-locking device for obtaining the Trendelenburg position, overhung by the " Pantophos " shadow-free light, in which heat and glare are eliminated. Among their large selection of stainless steel surgical instruments may be mentioned Souttar's craniotome, scalp clips, and steam cautery; Sargent's skull and laminectomy instruments; Tudor Edwards's thoracotomy instruments; Rowland's fasciatome for living sutures; Cope's universal " Duralumin " splint for Colles

quine" for malaria, and drew special attention to "Compral," a rapid analgesic without hypnotic effect; "Phanodorm," an hypnotic for general practice without cumulative action; "Theominal," a combination of luminal and theobromine for arteriosclerotic conditions; "Hexeton," a water-soluble synthetic camphor preparation for intramuscular and intravenous use; "Novasurol," a water-soluble preparation containing 33·9 per cent. of mercury in a complex non-ionisable form; and "Vigantol," a biologically standardised preparation of irradiated ergosterol, put up in pellets, ovoids, and a 1 per cent. solution in oil, of which 25 drops equals 10 mg. of vitamin D.—[39] Boots Pure Drug Co., Ltd. (Station-street, Nottingham), presented a series of pharmaceutical and toilet preparations, including "Columbrin," "Stabilarsan," "Thiostab," and "Bismostab."—[81] W. Bredt (41, Great Tower-street, E.C. 3) exhibited the "Ysates," dialysates from fresh plants, notably "Digitalysate," "Valerian-Digitalysate," and "Viscysate," prepared from *Viscum album* for conditions of high blood pressure. "Thilocologne," the preparation of ethyl chloride with eau-de-cologne, is now obtainable with a drop nozzle instead of a jet.—[20] Crookes Collosols (22, Chenies-street, W.C. 1) showed all their well-known colloidal preparations, such as argentum, iodine and manganese, and some new ones, including "Collosol Metallic Bismuth," a 5 per cent. preparation of finely divided metal which is usually absorbed within 10 days of injection, and "Collosol Mercurochrome" in dry scale preparation and sterile solution, standardised to obtain a definite percentage both of mercury and bromine. "Collosol Lactomagnesia" contains approximately 10 per cent. of magnesium hydroxide, and acts as an adsorber, a mild laxative, and a neutraliser without the evolution of gas. This firm also make some agreeable semi-toilet preparations, including "Collosol Argentum" tooth-paste and "Collosol Zinc" vanishing-cream.—[58] The British Drug Houses, Ltd. (Graham-street, N. 1), displayed their "Æther Puriss"; "Chloroform Puriss"; a non-clogging powdered liver extract, and their vitamin products, "Radiostol," "Radiostoleum," and "Radio-Malt," as well as "Caprokol," their urinary antiseptic; "Caprokol Antiseptic Solution S.T. 37," and their "Ergotoxin Phosphate," as used by A. Bourne and R. Burn.—[43] Burroughs, Wellcome and Co. (Snow Hill Buildings, E.C. 1) gave a prominent position to "Ephedrine," for asthma, hay fever, and leprosy; to "Allipol," the sodium salts of the less irritating fatty acids of hydnocarpus oil, and to "Avenyl," for leprosy complicated with syphilis. They also showed "Wellcome" liver extract and a representative display of standard drugs, sera, vaccines, and tuberculins.—[59] Evans Sons, Lescher and Webb, Ltd. (50, Bartholomew-close, E.C. 1), showed the various pharmaceutical specialties of this firm and the "Medi-soaps" manufactured by Charles Midgley, Ltd., of Manchester. Careful selection, preparation, and standardisation go to the making of this firm's gland products, which now include "Thymus Co.," "Mammary Co.," "Thyrosex Co.," and "Sexatones." This firm claim that their "Hepatex" is the cheapest and most concentrated liver extract on the market, one drachm being equivalent to two ounces of fresh liver. Their "Infundibulin" is now supplied in a special narrow-necked ampoule which can be opened without a file.—[35] Fassett and Johnson, Ltd. (86, Clerkenwell-road, E.C. 1), added to the well-known Angier's Emulsion and "California Syrup of Figs" a display of "Bemax," the new vitamin B preparation made from the detoxicated embryo of cereals.—[47] Ferris and Co., Ltd. (Union-street, Bristol), showed a series of fine chemicals and pharmaceutical preparations, particularly those of Martindale's "New Pharmacopœia"; also glandular products, cheap sterile accouchement outfits, and surgical dressings, specially set up in cabinets of "Ever-ready Caddies."—[27] Genatosan, Ltd. (Loughborough, Leicestershire), are very familiar for their "Sanatogen," "Genasprin" and "Formamint," and were displaying, as well as detoxicated and ordinary vaccines, their local immunity products, including an anticoryza vaccine spray.—[24] The Hoffmann-La Roche Chemical Works, Ltd. (51, Bowes-road, N. 13), draw special attention to their "Allonal" non-habit-forming hypnotic and analgesic, and "Isacen" non-toxic synthetic aperient, which gradually liberates di-hydroxyphenyl-isatin under the influence of the alkaline secretions of the intestine. "Somnifaine" is a liquid hypnotic of the barbituric group which can be administered orally, intramuscularly, or intravenously.—[10] J. F. Macfarlan and Co. (109, Abbey-hill, Edinburgh, and 32, Bethnal Green-road, E.1) showed a series of pure pharmaceutical chemicals, including alkaloids and capsules of amyl nitrite; anæsthetics, especially ethyl chloride, and dressings and ligatures.—[28] Oppenheimer, Son and Co., Ltd. (179, Queen Victoria-street, E.C. 4), stressed their new vitaminised preparations, such as "Vitad," a concentrate of the unsaponifiable fraction of cod-liver oil, 100 times stronger than the natural oil. This is supplied in "Palatinoids," equivalent to one teaspoonful and one tablespoonful respectively of the fresh oil. The little capsules make a most convenient vehicle of administration for young children. Irradiated ergosterol is also put up in "Palatinoid" form, and "Malt and Vitad" is a preparation equivalent to a 25 per cent. cod-liver oil and malt, but free from the unpleasant oily fraction. "Vitad" is also put into the well-known reconstructive food, "Roboleine."—[41] Parke, Davis and Co. (50-54, Beak-street, W. 1) demonstrated their recognised remedies, including quinine hydrochloride and urethane solution for sclerosing varicose veins, and also many recent introductions, such as "Adrephine," an aqueous solution for local use, combining the rapid relief of adrenalin with the sustained action of ephedrine; "Metatone," a tonic elixir containing vitamin B, nucleinic acid, and glycerophosphates; and "Paroidin," a standardised extract of bovine parathyroid glands for injection. "Oxytocin" is the pituitary substance that acts on involuntary muscle, and "Vasopressin" is the pituitary pressor principle. These two preparations will soon be on the market. Puerperal septicæmia streptococcus antitoxin is available for prophylaxis and therapeusis, while the series of "Immunogens," originating in the P., D. and Co. Laboratory, is now a long one.—[50] The Sandoz Chemical Works (5, Wigmore-street, W. 1) had on view their well-known products "Femergin," "Felamine" and "Bellafoline." "Allisatin" is their tasteless preparation of garlic. "Calcium-Sandoz" is obtained from an oxidation product of glucose by a special process and contains 13 per cent. of lime. "Sandoptal" (isobutyl-allyl-barbituric acid) is a new safe hypnotic, well tolerated by the aged.—[62] Schering-Kahlbaum, Ltd. (3, Lloyd's-avenue, E.C. 3), emphasised the value and safety of their non-narcotic analgesic "Veramon," and introduced "Solganal," a new gold product of low toxicity, particularly useful in leprosy, a 15-g. dose of which can be given with safety. Two other new products are "Vasano," camphoric acid salts of mandragora alkaloids, for train, air, and sea sickness, and "Synthalin B," a much less toxic product than the old Synthalin. "Atophan Balsam" is an amyl ester of "Atophan" for inunction.—[54] W. A. Wharram, Ltd. (31, Lady-lane, Leeds), make several popular pepsin preparations, such as "Liq. bismuth co. c. pepsin," and very many other therapeutic products. Mention may be made of ephedrine tablets for oral administration; "Linctus heroin hydrochlor. c. turpin. hyd."; "Syr. pulmonaria Co.," containing codeine phosphate, guaiacol, and calcium phosphate; "Ung. analgesic," a combination of methyl salicylate, menthol, eucalyptol and camphor; and "Ung. stimulans," a mustard preparation useful for rheumatic and neuralgic conditions.

2. *Special Drug Exhibits.*

[22] Anglo-American Oil Co., Ltd. (Albert-street, N.W. 1), pointed out that the price of their "Nujol" has now been considerably reduced, and that "Mistol"

formally opened. For a long time its financial basis was somewhat insecure, for the capital had been lost by the inflation of currency; but Prof. Kräpelin succeeded in interesting the Rockefeller Institution in the matter, and they furnished the necessary funds on condition that a certain sum was collected for working the institute. The fund thus opened found subscribers both in Germany and the United States, including Baron Krupp, of Essen, and Mr. James Loeb, of New York, and at last it has been possible to open the new building. It has departments for histopathology, topographical anatomy, serology, genetics, and psychology respectively. A chemical department under the celebrated analytical chemist, Prof. Willstätter, is to be opened in the near future. Besides the lavishly fitted laboratories there are rooms for collections and archives. At the opening ceremony, which was held in the presence of State and municipal authorities, Prof. Bouman, of Utrecht, presented a sum of M.20,000 (£500) in the name of a foreign committee. The Kräpelin gold medal was conferred upon Prof. Oscar Voigt, of Berlin, for his researches in the structure of the cerebral cortex.

Venereological Expedition to Russia.

The German Association for Aiding Scientific Research, in coöperation with the Health Department of the Soviet Republic and the Russian Academy of Sciences, has arranged an expedition to Russia for the study of syphilis. It is stated that in Europe syphilis has undergone an alteration under the influence of civilisation. It is thus essential to study it among a rather primitive population where it has been systematically combated for only a few years. As a suitable locality the Burjato Mongolian Republic situated beyond Lake Baikal has been chosen. Two German medical men went there last year to select a place for the research and they found that a town called Kulskoe would be convenient for the purpose because it possesses a hospital. The German Association has supplied the necessary apparatus and has fitted out a large serological laboratory. The Russian Government have promised to care for the housing and the maintenance of the staff, to have the hospital enlarged and modernised, and to facilitate as much as possible the work of the expedition. Acquired and hereditary syphilis will be studied by bacteriological and serological methods, and the results compared with those obtained in Europe. The expedition will include syphilologists, internists, and neurologists, and the German party, which will work under the direction of Prof. Hessner, of the Clinic for Venereal Diseases in Breslau, includes Dr. Klemm and Dr. Patzig, of the Institute for Cerebral Research in Berlin, Dr. Beringer, of the University Clinic for Nervous Diseases in Heidelberg, three women laboratory assistants, and an engineer to look after the apparatus. From Russia, where the Government shows great interest in the work, eight medical men, belonging to the staff of the State Institute for Venereal Diseases, will attach themselves to the expedition.

Dr. Wentzler, head of an infants' home in Berlin, says that in his institution the throat of every infant, even if healthy, is daily examined by a nurse, redness or any other abnormal condition being at once reported to the doctor. This makes it possible to detect suspected cases of illness at the earliest possible moment, and so prevent epidemics of diphtheria and scarlet fever from developing. Owing to the recent increase of diphtheria observed here, he recommends that the same measures should be taken in the schools. A nurse should be placed at the school entrance, whose duty it would be to examine the throat of every child. Where any reddening was discovered entrance to the school would be refused until the child had been examined by the school medical officer, who would decide whether an infectious disease was developing, and whether the child might be admitted to school.

MEDICINE AND THE LAW.

Imprisonment for "Nature Cure Practitioner."

MEDICAL practitioners are thinking quite as much of the public as of themselves when they deprecate the indiscriminate and unskilled use of ultra-violet ray and similar treatments. The possibilities of this kind of thing in the hands of amateurs are endless. During last month William Patrick Faulkner, a carpenter, was prosecuted at Marylebone Police-court on charges of obtaining certain sums by false pretences from Ernest Rose, another carpenter. It appeared that the two had entered into partnership and had opened a sun ray clinic and nature cure establishment in Praed-street, with a brass plate describing them as "Drs. Faulkner and Rose, nature cure practitioners and manipulative surgeons." Faulkner had made an agreement with Rose, which it was stated was signed "William Patrick Faulkner, M.D.," providing that each of them should put £50 into the concern and that they should share the profits. It was said that Faulkner told Rose he had just come from Ruskin College, Oxford, and was qualified as a doctor of medicine at King's College, also that he owned a house at Thornton Heath worth £1000. Believing these representations, Rose seems to have parted with about £130 in all. This included £4 which Faulkner seems to have obtained for the purpose of registering with the General Medical Council and 8 guineas for the purpose of registering with the L.C.C. Faulkner was not in fact on the Medical Register and did not pay the 8 guineas to the L.C.C. Mr. Wallace, appearing for the Director of Public Prosecutions, said Faulkner had been previously convicted for falsely pretending to be a registered medical practitioner, and also for obtaining money by false pretences. Mr. Wallace observed, as a warning of the dangers of sun ray treatment by unqualified persons, that one patient, who paid Faulkner a cheque for £6 and had treatment two or three times, was finally sent to hospital where she was found to be suffering from appendicitis. Had she continued her treatment with "Drs. Faulkner and Rose" much longer she would probably have ceased to require any treatment at all. Mr. Bingley, the magistrate, who passed sentence on Faulkner of three months' imprisonment with hard labour on each of two charges (making six months in all), agreed as to the grave danger to the public if people carried on such treatment unless properly qualified. The London County Council will presumably take note of the case. If their statutory powers of controlling such establishments are inadequate, they should be amplified forthwith.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. R. F. MacMahon is placed on Retd. List with the rank of Surg. Capt.

Surg. Comdrs.: R. J. G. Parnell to *Barham*, and as squadron medical officer and for specialist duties (on transfer of flag): and G. H. Hayes to *Warspite* (on transfer of flag).

Surg. Lt.-Comdr. S. R. Johnston to *Vulcan*, temp.

Surg. Lts.: J. J. Keevil to *Barham* (on transfer of flag): and C. H. Egan to *Warspite* (on transfer of flag).

Surg. Lt. (D) H. V. Pell to *Pembroke* for R.N. Barracks, Chatham.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lts. J. M. McC. Wright and J. Stephen to *Victory* for Haslar Hospl., for training.

Prob. Surg. Sub-Lts. E. G. Thomas, R. P. Davies, and D. A. Williams to *Victory* for Haslar Hosp. for training.

ROYAL ARMY MEDICAL CORPS.

Majs. to be Lt.-Cols.: H. T. Wilson, vice Lt.-Col. H. C. Sidgwick, to retd. pay: and R. C. Hallowes, vice Lt.-Col. (Bt. Col.) P. H. Henderson, promoted.

fracture; gynæcological instruments made for Messrs. Comyns Berkeley and Victor Bonney, and rectal instruments for Sir Charles Gordon Watson; the "Rotanda" blood transfusion syringe; a unique ratchet for retractors; British cystoscopes, and the light "Oslite" head-lamp.—[9] Albert Brown, Ltd. (Chancery-street, Leicester), showed a selection of stainless steel instruments and electric sterilisers, in particular Georg Wolf bladder instruments with Zeiss optics, a true-colour filter being built into them so that the eye can follow the movements of a lithotrite and see the bladder contents in their natural colours without fatigue. An interesting head lamp for ear, nose and throat work was fitted with an iris diaphragm and focusing lenses, so that the light could be intensified on a small area without dazzle.—[93A] Perhaps the most interesting exhibit in the whole show was that of Cameron's Surgical Speciality Co. (15, Stratford-place, W. 1). This apparatus provides, at a price well within the reach of the general practitioner, an endoscopic and inspection series which can be illuminated from any electric light plug and which the makers guarantee to be absolutely shock-proof and "fool-proof." The nasal sinuses can be transilluminated, root apices revealed, and foreign bodies detected; the retina can be lit up by pressing the bulb against the lower eyelid, and the veins are thrown into strong relief by pushing it into the soft tissues of a limb, so that intravenous injection in fat subjects loses its horrors. For the surgeon there are abdominal lights, which are guaranteed to withstand repeated sterilisation by boiling or steam pressure. The light used is of a wave-length peculiarly suitable for penetrating soft tissues. We advise every practitioner to inspect this for himself.—[76] C. W. Dixey and Son (13, St. Andrew's-crescent, Cardiff, and 3, New Bond-street, W. 1) showed a series of ophthalmoscopic instruments, particularly the Aves deviograph for testing the muscles of the eye.—[42] Down Bros., Ltd. (21 and 23, St. Thomas's-street, S.E. 1), included in their exhibit ox-bone plates and screws by Hamilton Bailey; Howarth's improved model of Chevalier Jackson's bronchoscopy and œsophagoscopy instruments; Souttar's counterpoised direct electric motor; Ivan Magill's portable intratracheal apparatus for anæsthesia; blood transfusion apparatus by Macintosh and others; and the "Up-to-Date" operation table with recent improvements.—[73] The Genito-Urinary Manufacturing Co., Ltd. (28A, Devonshire-street, W. 1), who are also agents for J. Eynard, Paris, showed a wide range of cystoscopes, bladder and kidney instruments, and diathermy apparatus.—[52 and 69] The Holborn Surgical Instrument Co., Ltd. (26, Thavies Inn, E.C. 1), had on view a large selection of modern surgical instruments in ordinary and stainless steel, including Kidd's female urethroscope; MacReynold's tonsil artery forceps; Guttmann's self-retaining vaginal speculum; the "Speclite" lamp, to clip on to the nose-piece of a shellite spectacle-frame, and the light, compact "Holborn" pocket head-lamp with elastic head-band.—[34] Mayer and Phelps (Chiron House, 59–61, New Cavendish-street, W. 1) pointed out their "Empire" operation-table, in which the Trendelenburg position can be obtained with perfect safety, and in which an improved lumbar bridge has been incorporated; Rowling's anæsthetic table; an outfit to supply a warmed atmosphere of either oxygen, nitrous oxide, or carbon dioxide, or of any percentage combination, with or without chloroform vapour; the "Chiron" fool-proof chloroform inhaler; Eadie's ligature forceps; and Canny Ryall's portable pelvic elevator.—[19] Rayner and Keeler, Ltd. (9, Vere-street, W. 1), showed various ophthalmoscopes and perimeters and a modified simple ophthalmic bracket which can be fastened above the patient's head and swung round in front of him. They also had on view various operating lamps and test types.—[12] The Surgical Manufacturing Co., Ltd. (83–85, Mortimer-street, W. 1), had a selection of new diagnostic instruments, including the Lilliput head-lamp; a new mercurial sphygmomanometer; a new combined ophthalmoscope, laryngoscope, and auroscope; the Servic steriliser for dressings, and a convenient new iodine container by means of which tincture of iodine can be carried about in a pocket and applied to the patient without staining of clothes or instruments.

(*To be concluded.*)

Special Articles.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Statistics of Venereal Disease.

IN December of last year a census of venereal patients was taken by the Health Office and the results have now been published. It is stated that the registration schedules sent to the medical profession have been answered by 93·6 per cent. of the general practitioners, 95·5 per cent. of the venereologists, and 97·5 per cent. of the hospitals and sanatoriums to whom they were sent, from which it is evident that the profession has taken great interest in the inquiry. The figures show that in Germany there were 18,608 patients who first came for treatment within the period Nov. 15th to Dec. 14th. Of these, 432 suffered from more than one venereal disease, 76 per cent. had gonorrhœa, 2·1 soft chancre, 5·3 per cent. primary syphilis, and 15·1 per cent. secondary syphilitic symptoms. Compared with 1919 the figures indicate a reduction by one half.

Phosgene Poisoning.

The regrettable accident at Hamburg, where an escape of phosgene caused the death of about 20 persons and the illness of some hundred others, has drawn our attention to the properties of this poison. Prof. Straub, of Munich, states that it is a very labile substance much used in the chemical industry—for instance, in the production of fuchsine. It may easily be condensed into a fluid and on contact with wet air this fluid is decomposed, developing chlorine and hydrochloric acid. These corrode the bronchi and produce broncho-pneumonia. Phosgene may also enter the living cells and bring about their death and has thus a delayed effect on the organism. The gas is produced when chloroform vapours come in contact with a flame, and intoxication from this cause used to occur sometimes in the days before operating theatres were fitted with electric light.

An International Conference on Scarlet Fever.

A conference of German and Russian medical savants, medical officers, and hospital physicians was held not long ago at Königsberg for the purpose of exchanging views on scarlet fever. Dr. Deicher (Berlin) said that in his experience antistreptococcal serum had proved very efficacious, no patient having died to whom the serum was administered in an early stage of the disease. When serum was used complications also had been rarer and less severe. Prof. Korschun (Moscow) and Dr. Bardach (Odessa) described methods of testing the efficacy of the individual serum. The Russian members of the congress reported that in their country prophylactic injections had been made in some 100,000 children and it had been ascertained that the protection lasted about nine months. This short duration is somewhat surprising as persons who have had scarlet fever are generally immune for a long period—even for the rest of their lives.

Cerebral Research.

The German Institute for Cerebral Research, founded by the late Prof. Kräpelin, has now been

It is not quite clear whether the S and R forms, which Commanders Dudley and Parker found to be contrasted in toxigenicity, were from different sources or were both derived in each instance from a single strain. In the former case the reasons for believing that they were all *C. diphtheriæ* are required to complete the evidence. Definition of a species in bacteria is difficult as Commander Dudley admits, and the assignment to *C. diphtheriæ* of a culture which is neither toxigenic nor descended from a toxigenic strain is a difficult and often unconvincing task.

The study of variation in bacteria is not yet very far advanced, but definite variation in antigenic constituents has already been described in several instances and found related to more obvious changes in character. There is also good evidence that antigenic composition may be closely connected with some factor in the composite character known as virulence. This is notably the case in the factors which have been studied both chemically and biologically by Avery, Heidelberger, and others—e.g., in the pneumococcus. It therefore seems probable that even in so variable a group as the bacteria tangible evidence of orderly variation will further accumulate and prove to be of wide theoretical and practical value.

I am, Sir, yours faithfully,
JOSEPH A. ARKWRIGHT.

Lister Institute, S.W., August 7th, 1928.

THE HEREDITARY AND CONSTITUTIONAL FACTOR IN ADDISON'S (PERNICIOUS) ANÆMIA.

To the Editor of THE LANCET.

SIR,—In your annotation last week on the Intestinal Bacteria in Pernicious Anæmia you state that the evidence for an hereditary or constiutional element in the disease is "rather nebulous." In a lecture published in THE LANCET five years ago I brought forward what I regarded as conclusive evidence in favour of such an hereditary or constitutional element. I believe this conception is of fundamental importance in the pathogenesis, prophylaxis, and treatment not only of Addison's anæmia (A.A.), but also of the associated nervous disease—subacute combined degeneration of the spinal cord (S.C.D.). I should like once again to summarise the evidence on the subject, as many further observations bearing on it have been made since the publication of my lecture.

The absence of hydrochloric acid from the gastric secretion appears to be the one essential predisposing cause of the two allied diseases. It is most frequently due to constitutional achylia gastrica, an inborn error of secretion, which is strictly comparable with Garrod's inborn errors of metabolism, such as cystinuria, alkaptonuria, and pentosuria. The error is one of function and not of structure, as the mucous membrane is normal and has a normal number of oxyntic cells. Achylia was present in 4 out of 100 healthy students examined by Bennett and Ryle at Guy's Hopsital: it occurs in early childhood, and is often present in several members of a family. Martinez has observed more than 20 such families, in one of which a great-grandmother, her daughter, four grandchildren, and five out of 13 great-grandchildren had achylia. I have had under my own care a brother and sister and two sisters with digestive symptoms caused by achylia gastrica.

The familial occurrence of achylia gastrica must be the explanation of the familial occurrence of A.A. which has been recorded by many observers. I have collected no less than 62 family histories from the literature, and 7 out of a series of 25 cases at New Lodge Clinic (27 per cent.) had one or more relations who had died of the disease.

Liepelt records the case of a mother and daughter both of whom suffered from S.C.D., and of a father and son with the disease, the grandfather having died of A.A. Willson, in 1912, described the case of a woman with S.C.D., two of whose maternal aunts had died of A.A. I have set with a similar family history in 4 out of 16 private patients with the disease: the mother of one and the paternal grandfather of another died of A.A. The most remarkable case was that of a doctor who died of S.C.D. associated with achylia gastrica and A.A.; his brother, father, paternal uncle, and paternal grandfather had all died of A.A. The brother of another doctor with severe A.A. and slight S.C.D. was found to have S.C.D. and achylia, but perfectly normal blood.

Five patients, who have consulted me for various conditions associated with achlorhydria, had one or more relatives who had died of A.A. I have collected records of 28 other cases in which A.A. in one or more members of a family was associated with achylia in others. The brother of a doctor of 42, who consulted me for digestive symptoms due to achlorhydria, had died at the age of 41 after being ill for 18 months with S.C.D. and terminal severe anæmia, and Evans has described the case of a man with S.C.D. and achlorhydria but no anæmia who had a sister with achlorhydria. Dorst has described a family, different members of which had either A.A. or S.C.D., or achlorhydria without nervous symptoms or anæmia.

A woman of 50, who was feeling quite well except for occasional diarrhœa and eczema, sought my advice mainly because she had become worried about herself owing to the number of relations on both sides of her family who had died of Addison's anæmia. Her sister, paternal grandmother, and a cousin of her father's had died of it, a paternal cousin of her own had it now, and her mother died of it. Her tongue, which had been sore from time to time for three years, had the characteristic appearance of Hunterian glossitis. Her hæmoglobin percentage was 76 with 4,100,000 red corpuscles per c.mm., and the average size of the red corpuscles was increased from the normal of 7·23 μ to 8·31 μ, but the red cells were otherwise perfectly normal in appearance. She had complete achlorhydria.

In connexion with the bacteriology of Addison's anæmia I regret that you make no reference to the important observations of Knott on the subject, most of which have been published in the Guy's Hospital Reports, as the more recent investigations of Dr. Stanley Davidson, which form the basis of your annotation, do little more than confirm his pioneer work.—I am, Sir, yours faithfully,

ARTHUR F. HURST.

New Lodge Clinic, Windsor Forest, August 6th, 1928.

INSTRUCTION IN PSYCHIATRY.

To the Editor of THE LANCET.

SIR,—Your review of Dr. H. J. Norman's book on Mental Disorders (July 21st, p. 125) will be approved by many of the older school of psychiatry. Yet it is disconcerting to find approval of a book, intended for students, on the ground that it does not deal with modern psychopathology. The most elementary knowledge of mental processes is withheld from our students. The metaphysical nature of the effort to correlate disordered conduct with disordered neurones, and its entire failure and practical futility in the psychoneuroses, are concealed from them. The mental attitude thus induced often persists throughout professional life in people of a certain temperament. Others make the discovery that something is wrong with their education or philosophy and feel helpless when faced with the many psychoneuroses of general practice, with only their traditional training in "neurones" to fall back upon. I am often asked by practitioners where they can learn about these matters, and where they can meet others of similar inclination to discuss their clinical difficulties and find out what is to be learnt from modern psychopathology. For this reason I ask the indulgence of your columns to notify that an effort is being made to form a small

COLONIAL MEDICAL SERVICES.

Dr. H. G. Holdbrook, Medical Officer, Federated Malay States, to be Senior Medical Officer, Selangor; Dr. W. H. Hart, Medical Officer, Federated Malay States, to be Senior Medical Officer, Perak.

Dr. S. P. Joseph, Mr. M. Jinadasa, and Dr. A. A. M. Weeraperumall, medical officers, to be Provincial Surgeons, Ceylon.

The following appointments have been made: Capt. P. H. Martin, Pathologist to the Institute of Medical Research, Federated Malay States; Dr. G. E. M. B. Dodds and Dr. C. E. M. J. Libert, Medical Officers, West African Medical Staff; Miss G. Lowe, Medical Officer, Nigeria; Dr. G. M. M. Menzies and Dr. W. Hunter, Medical Officers, West African Medical Staff.

DONATIONS AND BEQUESTS.—As the result of the recent Westminster Hospital Week, which was organised by representatives of the principal firms in Westminster, the institution has received £3500.—Mr. William Lyon, Carnoustie, left £500 each to the Dundee Royal Infirmary and the Forfar Infirmary to be applied to name a bed after him.—Mr. John Norman Dickinson, of Cockermouth, Cumberland, left £500 each to the Whitehaven and West Cumberland Infirmary and the Cumberland Infirmary, Carlisle, and £200 to St. Dunstan's Hostel for the Blind.—Mr. John Denniston Wilson, of Shaftesbury-avenue, London, and formerly of the Mercantile Bank of India, Batavia, Java, who left £57,188, after a number of private and other bequests amounting to £20,000, gave £1000 to the Hospital for Sick Children, Great Ormond-street, London, and the residue of the property to the executors for charities and hospitals.—Miss Alice Isabella Avery, of Athelney, Torquay, besides other bequests, left over £7000 to charities, including £1000 each to the Edinburgh Medical Missionary Society and the Children's Emigration Homes, and £500 to the Birmingham Medical Mission.—The Manchester Board of Guardians have decided to contribute £1000 towards cancer research.—Mr. Edward Palgrave Simpson, of Durham Villas, Phillimore-gardens, London, left, among other bequests, £2000 to St. Dunstan's Hostel for the Blind; £1200 to the Jenny Lind Infirmary, Norwich: £1000 each to Dr. Barnardo's Homes and the National Lifeboat Institution; £500 each to the West London Hospital, the National Industrial Home for Cripple Boys, Kensington, the Royal Hospital for Incurables, Putney, S.W., the Kensington District Nursing Association, the Church of England Homes for Waifs and Strays; £250 each to the Children's Country Holiday Fund, the Girls' Friendly Society, and the Holiday Cottage, Aston Clinton; £200 to the Norfolk and Norwich Hospital; £100 each to the After-Care Association, the Institution for the Indigent Blind, Norwich, the Eye Infirmary, Norwich, the Children's Convalescent Home, Lowestoft, and to the National Benevolent Institution.—Mr. Arthur Frederic Pope, of Manchester, among other bequests, left £500 to the Northern Counties Hospital for Incurables, £500 to the Manchester and Salford Hospital for Skin Diseases, and £500 to the Manchester Royal Infirmary.

"Audi alteram partem."

SMOOTH AND ROUGH VARIANTS OF BACTERIA.

To the Editor of THE LANCET.

SIR,—The letter by Surgeon-Commander Sheldon F. Dudley in THE LANCET of August 4th emphasises the present difficulties in attempting to analyse and classify the observed variation in bacteria. Names such as "smooth" and "rough" given to special instances of variation in the intestinal group have perhaps rather rashly been transferred to superficially similar variants in other groups. Morphological studies of colonies by Baerthlein and others, though of great importance in establishing that such variations do occur, do not of themselves lead very far on account of the great variety of the colonies, the uncertainty of the criteria based on colony morphology alone and the gradations between different types of colony.

It was in the hope of advancing the study of variation further along the path indicated by Baerthlein that the present writer described a particular kind of variant distinguished by three somewhat diverse characters—namely, irregularity of the edge and surface of the colony, agglutinability in salt solution, and alteration in the agglutination by serum. Though this group of characters which constituted the variant called "rough" in *Bacillus dysenteriæ*, *B. typhosus* and allied bacteria appears to represent a fundamentally changed race, still the change is not always complete and the three characters may to some extent vary independently. This also applies to a fourth character—absence of pathogenicity—which has since been determined in certain "rough" variants. The independent variability of the characters is perhaps often not so much due to the want of uniformity in the elementary factors in a given variant as to the observed characters not being sufficiently elementary to correspond exactly to the fundamental factors. Further observation and scrutiny tends to reveal the really essential units which themselves are concerned in variation.

As an example of diverse variants which are superficially alike may be mentioned the "medusa-head" colonies in *B. anthracis*, *B. subtilis*, streptococcus, and occasionally in *B. typhosus*. The appearance of this form of colony is due to growth of the bacteria in long chains or threads often without any other constantly associated change in the antigenic or other characters. Such colonies are probably in part responsible, as has recently been remarked by F. W. Andrewes, for the different observations as regards virulence, &c., obtained with colonies which appear alike. On account of the irregularity of surface "medusa-head" colonies have sometimes been called "rough" and a resemblance in virulence, antigenic properties, &c., to other "rough"-looking colonies, which are essentially very different, is expected unwarrantably. It is surely undesirable to decry the quest for "laws" or "rules" in variation because apparent exceptions occur, considering the complicated biological processes involved.

The promised publication by Commanders Dudley and Parker on the toxigenicity of different colony forms of *Corynebacterium diphtheriæ* will be welcomed by other bacteriologists, especially if it is possible to identify the forms which they have found with the two well-known colony variants formerly described by Cobbett and by Sclawyk and Manacatide, who did not find any change in virulence in their variants, or with the "non-virulent" variant with a special colony form recently obtained by M. Cowan Maitland from several virulent strains. In these researches the authors procured the variants pari passu with the more normal forms from virulent cultures.

in 1926. The Board of Health considered that the increased number was a sign of increased efficiency in the inspectorate, and if that was so, he was glad, but it also showed that there was still a substantial amount of tuberculosis among cattle in Scotland. In view of the danger to young children, especially the poorest, it was well that effective steps should be taken to deal with the matter. Even the Empire Marketing Board were now publishing placards inviting people to use more milk, but in view of the fact that the former percentage of tuberculous milk was 8 per cent., he would hesitate to recommend anyone with young children to use ordinary milk unless he was satisfied—which he was not—that that percentage had been reduced almost to vanishing point. It would be a good thing if the right hon. gentleman could reassure the public mind as to the quality of the milk, in view of the propaganda that was being carried on for increased consumption. The report contained a chapter on venereal disease. What was the position of the department in regard to that subject? The chapter in the report was very cautiously written, but it showed that the technical heads of the department were not at all satisfied with the position. The large sum of £60,000 or £70,000 was being spent in Scotland alone in dealing with this disease, and something like £600,000 throughout the Kingdom. Yet in Scotland the percentage of defaulters was 51. That showed an appalling waste of public money. The local authorities in Scotland were of opinion that the present arrangements were not satisfactory or efficient.

Coöperation Between Hospitals.

The question of coöperation between hospitals was being very carefully considered by many bodies, both in England and Scotland. The voluntary hospital managers were very much concerned at the present position, and the question of coöperation between the voluntary, municipal, and poor-law hospitals was bound to arise in connexion with the proposed local government changes. In Aberdeen there was an arrangement that seemed to be very desirable. The parish councils there had handed their hospitals over to the Public Health Committee of the town council, and the whole of the public health accommodation there was being administered by one authority. In Glasgow, also, there was a working arrangement of a similar kind. Many of the poor-law hospitals in Scotland were not well equipped or adequately staffed, and the association, with the municipal services, and with the staffs of the various voluntary hospitals, was bound to improve their efficiency. He was glad that the Department seemed inclined to encourage that. He would like to ask if the Secretary for Scotland had any information to give in regard to Craigleith Hospital. The position of that institution and Craiglockhart Hospital, he understood, was being considered and, in view of the shortage of beds in Edinburgh Infirmary, it would be as well if some arrangement of that kind were made as soon as possible. The report of the Mackenzie Committee stated that there was a shortage of 3000 beds in Scotland two years ago, and the position was not any better to-day. Did the Minister consider that adequate arrangements had now been made, or were likely to be made, to provide at an early date a proper number of beds? The Scottish Committee of the British Hospitals Association had set up five local committees for coördinating the various hospital activities, and there was also a liaison committee between those bodies and the Department. Why were there no representatives of the municipalities on that liaison committee? This ought not to be a matter purely between the managers of voluntary hospitals and the Department: the municipal medical services ought to be represented in any working arrangement of this kind, because there was in these negotiations a danger of magnifying to too great an extent the importance of the voluntary principle and to say that it must be preserved at all costs. The first consideration must be the efficiency of the hospital service and the supply of an adequate number of beds. While they acknowledged the important work which the voluntary hospitals had done, they regarded the voluntary agent as being the pioneer, and considered that when the necessity of the work was evident it should be done by the public authority, so that adequate medical attention might be given to all classes of the community.

What had happened to the report of the Departmental Committee on Maternal Mortality which was issued about 18 months ago? How many of its recommendations had been put into operation? There was no doubt that this subject must ultimately be dealt with by municipal maternity services, and by ensuring coöperation between doctors and midwives, and between the ante-natal services and the other public health services. He could not now go into the large question of the nutrition of school-children, but he called attention to the fact that last year 6·4 per cent. of school-children in Scotland were in a state of nutrition below the average, while 1·5 per 1000 were in a state of very poor nutrition. Was the Board of Health urging local authorities to put into operation the whole of their powers for feeding necessitous children? With all the poverty and misfortune in Scotland there was money enough to feed the children. The same consideration applied to the questions of the dental treatment of school children and treatment of adenoids, tonsils, and so on. There was no doubt that many of these children were suffering in health because of defects which, if their parents were in a better position in society and had more money, would be remedied as a matter of course: but because the parents were unable to afford it, and because the school medical service was not big enough and had not sufficient resources, they were left to drift very often into a state of chronic ill-health.

Mr. MACQUISTEN attributed the poverty of some districts of Southern Scotland to Irish incursion.

Mr. JAMES STEWART drew attention to the alarming figures in the report with reference to tuberculosis, both case-rate and death-rate being on the ascendant, especially in the Highlands and Islands.

Mr. T. HENDERSON called attention to the inadequacy of the efforts to suppress venereal disease in Scotland.

Reply to the Debate.

Major ELLIOT (Under-Secretary of State for Scotland) in replying to the debate, said that the Board of Health were keeping an anxious watch on the health of Scotland to see if deterioration was taking place—that deterioration which indeed one would expect from the long-continued industrial depression. They had not yet any evidence to lead to the conclusion that deterioration was taking place. The reports of medical officers of health on the school population did not indicate any deterioration in the health of the children of Scotland generally. They had kept a watchful eye on the vital statistics of the country. It was true that last year the pulmonary tuberculosis figures were higher than those of the year before, but they were lower than they had been for any year up to that time, lower than in 1921, 1922, 1923, 1924, and 1925. Non-pulmonary tuberculosis continued to fall and was lower last year than ever before. They all agreed as to the tremendous struggle through which industrial Scotland was passing and the Government were not blind to the situation. They recognised the urgent necessity to deal with it by legislation which would be laid before the House before the end of the present year. Dr. Shiels had said that the percentage of underfed and badly-fed children was too high and he (Major Elliot) agreed with him. They must continue to do their utmost by improving the school medical services and by tightening up regulations to make sure that the Education Act was carried out and that every child got sufficient nourishment to enable it to take advantage of education. There was no divergence of opinion between the Secretary of State and his advisers on the question of venereal disease. The report made it quite clear that in the opinion of the Secretary of State the time had not come to ask the House for further compulsory powers until they were sure that the powers already entrusted to the local authorities by the Government had been utilised *to the full.*

Dr. SHIELS said that the point he wished to make was that there was a divergence of opinion between the Scottish Board of Health and the English Ministry of Health and not between the Secretary for Scotland and his advisers.

Major ELLIOT said he could assure the hon. gentleman that the Secretary for Scotland was in no way inclined to defer to the opinion of the English Minister. He considered the matter on its merits in consultation with his technical advisers and in accordance with their advice he came to the conclusion mentioned in the report. The Scottish Board of Health were not flinching from drastic action to make sure that the milk-supplies were as pure as could reasonably be managed. In reply to Dr. Shiels's question as to the medical member of the Board of Health, everyone knew that Sir Leslie Mackenzie had now retired, and it was right that Parliament should take note of that fact and remember, with gratitude, the great work that he had done for the health of the people of Scotland—(general cheers)—during the many years that he had been entrusted with that duty. The reason that a new medical member had not yet been appointed to take his place was simply that the Bill for the Reorganisation of Offices in Scotland had not yet received the Royal Assent. As soon as that Bill became an Act of Parliament the Secretary for Scotland would proceed with the utmost expedition to make the new appointment. He had nothing further to report for the moment in regard to hospitals, but the proposals that Dr. Shiels had brought forward would be considered. He was not able to say that the shortage of hospital beds had been remedied, but an improvement was being effected almost monthly, with the provision of increased

society with these aims and I shall be pleased to hear from any would-be supporters.

I am, Sir, yours faithfully,

Harley-street, W., July 24th, 1928. ESTELLE COLE.

*** Dr. Cole raises a very important point, but our reviewer has not exactly approved the absence of teaching in psychopathology so much as conveyed the opinion that so important and difficult a subject should be properly taught or left alone. We have seen instructions in manuals of psychiatry which could have but little relation to the counsels which would be given by lectures to students out of first-hand experience.—ED. L.

CANCER AND THE BLOOD-GROUPS.

To the Editor of THE LANCET.

SIR,—In general practice there are occasions in which cancer appears to be a family disease, and on the other hand, some family strains appear to be immune. If not already dealt with and known, an investigation of the relative incidence of cancer in the different blood-groups might prove interesting.

I am, Sir, yours faithfully,

HOME PRODUCTION OF COCAINE.

To the Editor of THE LANCET.

SIR,—In an annotation entitled The Traffic in Narcotic Drugs, which appeared in your last issue (p. 236), you refer to the manufacture of cocaine in this country and state that hitherto there has been no production of cocaine from the leaves, or by refining crude cocaine, in Great Britain, adding that in 1927 a licence was granted to a firm of manufacturing chemists to carry on experiments in such manufacture. You will be interested to learn that cocaine was manufactured by us in 1903 at the Wellcome Chemical Works, Dartford. We were granted a Home Office licence in March, 1917, and have manufactured many thousands of ounces of cocaine at Dartford.

We are, Sir, yours faithfully,

BURROUGHS WELLCOME AND CO.

SMOKE ABATEMENT INQUIRY AT BRADFORD.—Mr. F. O. Sandford, of the Ministry of Health, recently conducted an inquiry at Bradford into the application by various West Riding authorities for new by-laws on the smoke nuisance. The proposed by-laws provide that the emission of black smoke for two minutes in the aggregate within any continuous period of 30 minutes should constitute a nuisance. The authorities applying for the by-laws were Bradford, Huddersfield, Leeds, Halifax, Dewsbury, Batley, Spenborough, and Guiseley. In support of the application it was stated that the decision to apply for new by-laws arose out of a recommendation by a regional smoke abatement committee for the West Riding of Yorkshire, which represented something like 100 local authorities and a million people, and that committee approved of the terms of the suggested by-laws. In Bradford alone there were 438 industrial chimneys and 1330 furnaces. During the last seven years there had been 73 proved cases of smoke offences, and one firm had been prosecuted 70 times. The standard adopted in regard to smoke nuisance varied widely in the districts concerned. Amongst others evidence in support of the application was given by the medical officers of Bradford and Leeds. In opposition to the proposed by-laws by various trade associations and chambers of commerce it was stated that it had been proved by experience by firms with the most modern plant that it was impossible to comply with the terms of the by-laws. It could not be worked in practice, except by imposing a tremendous burden on industry. It was contended that the existing local Acts in Bradford were quite sufficient to deal with the problem.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

PROROGATION OF PARLIAMENT.

PARLIAMENT was prorogued on Friday, August 3rd, until Tuesday, Nov. 6th. The Royal Assent was given by Royal Commission to a large number of Acts passed during the past session.

HEALTH ADMINISTRATION IN SCOTLAND.

On Tuesday, July 31st, the House of Commons went into Committee of Supply on a vote of £2,037,515 for the salaries and expenses of the Scottish Board of Health. Mr. JAMES HOPE was in the chair.

Mr. W. ADAMSON said the subject he wished to raise was the deterioration of the physical condition of the Scottish people due to the inadequate provision that was being made for them by the Scottish Board of Health. There were a number of causes that were leading to the poverty-stricken conditions in which a large number of Scottish people found themselves to-day, but the main cause was unemployment. That problem was even more severe in Scotland than it was in England. Nearly one-third fewer miners were being employed to-day than were at work in 1924. In many cases the unemployed persons had been out of work for a considerable time. In Glasgow the period of unemployment ranged from six months to six years. This problem was bearing very heavily upon the local authorities in Scotland, and particularly upon the parish councils. He wished to impress upon the Secretary for Scotland that the provisions made in these estimates to deal with the problem of poverty and distress in Scotland were quite inadequate. In last year's estimates they had £260,000 in grants made to parish councils in respect of poor relief, but this year there was not a single penny. He appealed to the Secretary for Scotland to examine this problem closely with a view to more being done by the Scottish Board of Health to enable Scotland to shoulder this grievous burden.

Dr. DRUMMOND SHIELS said that that was the last time they would discuss the report as the report of the Scottish Board of Health. In the valedictory foreword which the members of the Board had inserted in the report they expressed the belief that the efficiency of the work of the department in future would not be inferior in any way to that of the Board. Although Labour Members had strongly opposed the change that was to be made they sincerely wished that the high standard of efficiency associated with the Board of Health would be maintained under the new régime. He wished to know what was the position with regard to the vacancy in the medical membership of the Board. It was known for a long while in advance that Sir Leslie Mackenzie was going to resign. Could the Secretary for Scotland now intimate who his successor would be? He sincerely hoped that when the appointment was made it would be found that a member of the present staff had been promoted to the position.

Milk-supply and Tuberculosis.

The question of the milk-supply and tuberculosis was, he said, dealt with in the report. Undoubtedly under the effective administration of Dr. Leighton a very great improvement had taken place in the milk-supply of Scotland. It was much cleaner and better than it had ever been. There had been a gratifying increase in the quantity of licensed graded milk, but it still amounted to little more than 1 per cent. of the whole milk used in Scotland. The nomenclature of the grades was very misleading. There was no doubt that Grade A in bulk, which was only the third of the qualities, was considered by many people to be the first quality, while the tuberculin-tested milk had not got its proper position in the public mind because of confusion of Grade A milk with that of the highest quality. Some revision of that nomenclature ought to be made, so that the public could understand properly what the position was. He would like to know if the Secretary for Scotland was satisfied with regard to pasteurised milk? If pasteurisation was carried out effectively this milk was safe, but there was a great liability for pasteurisation to be done ineffectively, and to be a danger rather than a help by misleading people as to its safety. The report did not deal with the point. Was any definite standard laid down; if so, was it being enforced; and had there been any cases where pasteurisation, which was becoming almost the most popular form of protecting milk, was regarded by the Department as being wholly safe and to be trusted?

The report stated that last year 2240 animals, mostly cows, were condemned as tuberculous, compared with 1852

in 1926. The Board of Health considered that the increased number was a sign of increased efficiency in the inspectorate, and if that was so, he was glad, but it also showed that there was still a substantial amount of tuberculosis among cattle in Scotland. In view of the danger to young children, especially the poorest, it was well that effective steps should be taken to deal with the matter. Even the Empire Marketing Board were now publishing placards inviting people to use more milk, but in view of the fact that the former percentage of tuberculous milk was 8 per cent., he would hesitate to recommend anyone with young children to use ordinary milk unless he was satisfied—which he was not—that that percentage had been reduced almost to vanishing point. It would be a good thing if the right hon. gentleman could reassure the public mind as to the quality of the milk, in view of the propaganda that was being carried on for increased consumption. The report contained a chapter on venereal disease. What was the position of the department in regard to that subject? The chapter in the report was very cautiously written, but it showed that the technical heads of the department were not at all satisfied with the position. The large sum of £60,000 or £70,000 was being spent in Scotland alone in dealing with this disease, and something like £600,000 throughout the Kingdom. Yet in Scotland the percentage of defaulters was 51. That showed an appalling waste of public money. The local authorities in Scotland were of opinion that the present arrangements were not satisfactory or efficient.

Coöperation Between Hospitals.

The question of coöperation between hospitals was being very carefully considered by many bodies, both in England and Scotland. The voluntary hospital managers were very much concerned at the present position, and the question of coöperation between the voluntary, municipal, and poor-law hospitals was bound to arise in connexion with the proposed local government changes. In Aberdeen there was an arrangement that seemed to be very desirable. The parish councils there had handed their hospitals over to the Public Health Committee of the town council, and the whole of the public health accommodation there was being administered by one authority. In Glasgow, also, there was a working arrangement of a similar kind. Many of the poor-law hospitals in Scotland were not well equipped or adequately staffed, and the association, with the municipal services, and with the staffs of the various voluntary hospitals, was bound to improve their efficiency. He was glad that the Department seemed inclined to encourage that. He would like to ask if the Secretary for Scotland had any information to give in regard to Craigleith Hospital. The position of that institution and Craiglockhart Hospital, he understood, was being considered and, in view of the shortage of beds in Edinburgh Infirmary, it would be as well if some arrangement of that kind were made as soon as possible. The report of the Mackenzie Committee stated that there was a shortage of 3600 beds in Scotland two years ago, and the position was not any better to-day. Did the Minister consider that adequate arrangements had now been made, or were likely to be made, to provide at an early date a proper number of beds? The Scottish Committee of the British Hospitals Association had set up five local committees for coördinating the various hospital activities, and there was also a liaison committee between those bodies and the Department. Why were there no representatives of the municipalities on that liaison committee? This ought not to be a matter purely between the managers of voluntary hospitals and the Department; the municipal medical services ought to be represented in any working arrangement of this kind, because there was in these negotiations a danger of magnifying to too great an extent the importance of the voluntary principle and to say that it must be preserved at all costs. The first consideration must be the efficiency of the hospital service and the supply of an adequate number of beds. While they acknowledged the important work which the voluntary hospitals had done, they regarded the voluntary agent as being the pioneer, and considered that when the necessity of the work was evident it should be done by the public authority, so that adequate medical attention might be given to all classes of the community.

What had happened to the report of the Departmental Committee on Maternal Mortality which was issued about 18 months ago? How many of its recommendations had been put into operation? There was no doubt that this subject must ultimately be dealt with by municipal maternity services, and by ensuring coöperation between doctors and midwives, and between the ante-natal services and the other public health services. He could not now go into the large question of the nutrition of school-children, but he called attention to the fact that last year 6·4 per cent. of school-children in Scotland were in a state of nutrition below the average, while 1·5 per 1000 were in a state of very poor nutrition. Was the Board of Health urging local authorities to put into operation the whole of their powers for feeding necessitous children? With all the poverty and misfortune in Scotland there was money enough to feed the children. The same consideration applied to the questions of the dental treatment of school children and treatment of adenoids, tonsils, and so on. There was no doubt that many of these children were suffering in health because of defects which, if their parents were in a better position in society and had more money, would be remedied as a matter of course; but because the parents were unable to afford it, and because the school medical service was not big enough and had not sufficient resources, they were left to drift very often into a state of chronic ill-health.

Mr. MACQUISTEN attributed the poverty of some districts of Southern Scotland to Irish incursion.

Mr. JAMES STEWART drew attention to the alarming figures in the report with reference to tuberculosis, both case-rate and death-rate being on the ascendant, especially in the Highlands and Islands.

Mr. T. HENDERSON called attention to the inadequacy of the efforts to suppress venereal disease in Scotland.

Reply to the Debate.

Major ELLIOT (Under-Secretary of State for Scotland) in replying to the debate, said that the Board of Health were keeping an anxious watch on the health of Scotland to see if deterioration was taking place—that deterioration which indeed one would expect from the long-continued industrial depression. They had not yet any evidence to lead to the conclusion that deterioration was taking place. The reports of medical officers of health on the school population did not indicate any deterioration in the health of the children of Scotland generally. They had kept a watchful eye on the vital statistics of the country. It was true that last year the pulmonary tuberculosis figures were higher than those of the year before, but they were lower than they had been for any year up to that time, lower than in 1921, 1922, 1923, 1924, and 1925. Non-pulmonary tuberculosis continued to fall and was lower last year than ever before. They all agreed as to the tremendous struggle through which industrial Scotland was passing and the Government were not blind to the situation. They recognised the urgent necessity to deal with it by legislation which would be laid before the House before the end of the present year. Dr. Shiels had said that the percentage of underfed and badly-fed children was too high and he (Major Elliot) agreed with him. They must continue to do their utmost by improving the school medical services and by tightening up regulations to make sure that the Education Act was carried out and that every child got sufficient nourishment to enable it to take advantage of education. There was no divergence of opinion between the Secretary of State and his advisers on the question of venereal disease. The report made it quite clear that in the opinion of the Secretary of State the time had not come to ask the House for further compulsory powers until they were sure that the powers already entrusted to the local authorities by the Government had been utilised to the full.

Dr. SHIELS said that the point he wished to make was that there was a divergence of opinion between the Scottish Board of Health and the English Ministry of Health and not between the Secretary for Scotland and his advisers.

Major ELLIOT said he could assure the hon. gentleman that the Secretary for Scotland was in no way inclined to defer to the opinion of the English Minister. He considered the matter on its merits in consultation with his technical advisers and in accordance with their advice he came to the conclusion mentioned in the report. The Scottish Board of Health were not flinching from drastic action to make sure that the milk-supplies were as pure as could reasonably be managed. In reply to Dr. Shiels's question as to the medical member of the Board of Health, everyone knew that Sir Leslie Mackenzie had now retired, and it was right that Parliament should take note of that fact and remember, with gratitude, the great work that he had done for the health of the people of Scotland—(general cheers)—during the many years that he had been entrusted with that duty. SMOKE ABATEMENT INQUIRY AT BRADFORD.—Mr. F. O. Sandford, of the Ministry of Health, recently conducted an inquiry at Bradford into the application by various West Riding authorities for new by-laws on the smoke nuisance. The proposed by-laws provide that the emission of black smoke for two minutes in the aggregate within any continuous period of 30 minutes should constitute a nuisance. The authorities applying for the by-laws were Bradford, Huddersfield, Leeds, Halifax, Dewsbury, Batley, Spenborough, and Guiseley. In support of the application it was stated that the decision to apply for new by-laws arose out of a recommendation by a regional smoke abatement committee for the West Riding of Yorkshire, which represented something like 100 local authorities and a million people, and that committee approved of the terms of the suggested by-laws. In Bradford alone there were 438 industrial chimneys and 1330 furnaces. During the last seven years there had been 73 proved cases of smoke offences, and one firm had been prosecuted 70 times. The standard adopted in regard to smoke nuisance varied widely in the districts concerned. Amongst others evidence in support of the application was given by the medical officers of Bradford and Leeds. In opposition to the proposed by-laws by various trade associations and chambers of commerce it was stated that it had been proved by experience by firms with the most modern plant that it was impossible to comply with the terms of the by-laws. It could not be worked in practice, except by imposing a tremendous burden on industry. It was contended that the existing local Acts in Bradford were quite sufficient to deal with the problem.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

PROROGATION OF PARLIAMENT.

PARLIAMENT was prorogued on Friday, August 3rd, until Tuesday, Nov. 6th. The Royal Assent was given by Royal Commission to a large number of Acts passed during the past session.

HEALTH ADMINISTRATION IN SCOTLAND.

On Tuesday, July 31st, the House of Commons went into Committee of Supply on a vote of £2,037,515 for the salaries and expenses of the Scottish Board of Health. Mr. JAMES HOPE was in the chair.

Mr. W. ADAMSON said the subject he wished to raise was the deterioration of the physical condition of the Scottish people due to the inadequate provision that was being made for them by the Scottish Board of Health. There were a number of causes that were leading to the poverty-stricken conditions in which a large number of Scottish people found themselves to-day, but the main cause was unemployment. That problem was even more severe in Scotland than it was in England. Nearly one-third fewer miners were being employed to-day than were at work in 1924. In many cases the unemployed persons had been out of work for a considerable time. In Glasgow the period of unemployment ranged from six months to six years. This problem was bearing very heavily upon the local authorities in Scotland, and particularly upon the parish councils. He wished to impress upon the Secretary for Scotland that the provisions made in these estimates to deal with the problem of poverty and distress in Scotland were quite inadequate. In last year's estimates they had £260,000 in grants made to parish councils in respect of poor relief, but this year there was not a single penny. He appealed to the Secretary for Scotland to examine this problem closely with a view to more being done by the Scottish Board of Health to enable Scotland to shoulder this grievous burden.

Dr. DRUMMOND SHIELS said that that was the last time they would discuss the report as the report of the Scottish Board of Health. In the valedictory foreword which the members of the Board had inserted in the report they expressed the belief that the efficiency of the work of the department in future would not be inferior in any way to that of the Board. Although Labour Members had strongly opposed the change that was to be made they sincerely wished that the high standard of efficiency associated with the Board of Health would be maintained under the new régime. He wished to know what was the position with regard to the vacancy in the medical membership of the Board. It was known for a long while in advance that Sir Leslie Mackenzie was going to resign. Could the Secretary for Scotland now intimate who his successor would be? He sincerely hoped that when the appointment was made it would be found that a member of the present staff had been promoted to the position.

Milk-supply and Tuberculosis.

The question of the milk-supply and tuberculosis was, he said, dealt with in the report. Undoubtedly under the effective administration of Dr. Leighton a very great improvement had taken place in the milk-supply of Scotland. It was much cleaner and better than it had ever been. There had been a gratifying increase in the quantity of licensed graded milk, but it still amounted to little more than 1 per cent. of the whole milk used in Scotland. The nomenclature of the grades was very misleading. There was no doubt that Grade A in bulk, which was only the third of the qualities, was considered by many people to be the first quality, while the tuberculin-tested milk had not got its proper position in the public mind because of confusion of Grade A milk with that of the highest quality. Some revision of that nomenclature ought to be made, so that the public could understand properly what the position was. He would like to know if the Secretary for Scotland was satisfied with regard to pasteurised milk? If pasteurisation was carried out effectively this milk was safe, but there was a great liability for pasteurisation to be done ineffectively, and to be a danger rather than a help by misleading people as to its safety. The report did not deal with the point. Was any definite standard laid down; if so, was it being enforced; and had there been any cases where pasteurisation, which was becoming almost the most popular form of protecting milk, was regarded by the Department as being wholly safe and to be trusted?

The report stated that last year 2240 animals, mostly cows, were condemned as tuberculous, compared with 1852

in 1926. The Board of Health considered that the increased number was a sign of increased efficiency in the inspectorate, and if that was so, he was glad, but it also showed that there was still a substantial amount of tuberculosis among cattle in Scotland. In view of the danger to young children, especially the poorest, it was well that effective steps should be taken to deal with the matter. Even the Empire Marketing Board were now publishing placards inviting people to use more milk, but in view of the fact that the former percentage of tuberculous milk was 8 per cent., he would hesitate to recommend anyone with young children to use ordinary milk unless he was satisfied—which he was not—that that percentage had been reduced almost to vanishing point. It would be a good thing if the right hon. gentleman could reassure the public mind as to the quality of the milk, in view of the propaganda that was being carried on for increased consumption. The report contained a chapter on venereal disease. What was the position of the department in regard to that subject? The chapter in the report was very cautiously written, but it showed that the technical heads of the department were not at all satisfied with the position. The large sum of £60,000 or £70,000 was being spent in Scotland alone in dealing with this disease, and something like £600,000 throughout the Kingdom. Yet in Scotland the percentage of defaulters was 51. That showed an appalling waste of public money. The local authorities in Scotland were of opinion that the present arrangements were not satisfactory or efficient.

Coöperation Between Hospitals.

The question of coöperation between hospitals was being very carefully considered by many bodies, both in England and Scotland. The voluntary hospital managers were very much concerned at the present position, and the question of coöperation between the voluntary, municipal, and poor-law hospitals was bound to arise in connexion with the proposed local government changes. In Aberdeen there was an arrangement that seemed to be very desirable. The parish councils there had handed their hospitals over to the Public Health Committee of the town council, and the whole of the public health accommodation there was being administered by one authority. In Glasgow, also, there was a working arrangement of a similar kind. Many of the poor-law hospitals in Scotland were not well equipped or adequately staffed, and the association, with the municipal services, and with the staffs of the various voluntary hospitals, was bound to improve their efficiency. He was glad that the Department seemed inclined to encourage that. He would like to ask if the Secretary for Scotland had any information to give in regard to Craigleith Hospital. The position of that institution and Craiglockhart Hospital, he understood, was being considered and, in view of the shortage of beds in Edinburgh Infirmary, it would be as well if some arrangement of that kind were made as soon as possible. The report of the Mackenzie Committee stated that there was a shortage of 3600 beds in Scotland two years ago, and the position was not any better to-day. Did the Minister consider that adequate arrangements had now been made, or were likely to be made, to provide at an early date a proper number of beds? The Scottish Committee of the British Hospitals Association had set up five local committees for coördinating the various hospital activities, and there was also a liaison committee between those bodies and the Department. Why were there no representatives of the municipalities on that liaison committee? This ought not to be a matter purely between the managers of voluntary hospitals and the Department: the municipal medical services ought to be represented in any working arrangement of this kind, because there was in these negotiations a danger of magnifying to too great an extent the importance of the voluntary principle and to say that it must be preserved at all costs. The first consideration must be the efficiency of the hospital service and the supply of an adequate number of beds. While they acknowledged the important work which the voluntary hospitals had done, they regarded the voluntary agent as being the pioneer, and considered that when the necessity of the work was evident it should be done by the public authority, so that adequate medical attention might be given to all classes of the community.

What had happened to the report of the Departmental Committee on Maternal Mortality which was issued about 18 months ago? How many of its recommendations had been put into operation? There was no doubt that this subject must ultimately be dealt with by municipal maternity services, and by ensuring coöperation between doctors and midwives, and between the ante-natal services and the other public health services. He could not now go into the large question of the nutrition of school-children, but he called attention to the fact that last year 6·4 per cent. of school-children in Scotland were in a state of nutrition below the average, while 1·5 per 1000 were in a state of very poor nutrition. Was the Board of Health urging local authorities to put into operation the whole of their powers for feeding necessitous children? With all the poverty and misfortune in Scotland there was money enough to feed the children. The same consideration applied to the questions of the dental treatment of school children and treatment of adenoids, tonsils, and so on. There was no doubt that many of these children were suffering in health because of defects which, if their parents were in a better position in society and had more money, would be remedied as a matter of course; but because the parents were unable to afford it, and because the school medical service was not big enough and had not sufficient resources, they were left to drift very often into a state of chronic ill-health.

Mr. MACQUISTEN attributed the poverty of some districts of Southern Scotland to Irish incursion.

Mr. JAMES STEWART drew attention to the alarming figures in the report with reference to tuberculosis, both case-rate and death-rate being on the ascendant, especially in the Highlands and Islands.

Mr. T. HENDERSON called attention to the inadequacy of the efforts to suppress venereal disease in Scotland.

Reply to the Debate.

Major ELLIOT (Under-Secretary of State for Scotland) in replying to the debate, said that the Board of Health were keeping an anxious watch on the health of Scotland to see if deterioration was taking place—that deterioration which indeed one would expect from the long-continued industrial depression. They had not yet any evidence to lead to the conclusion that deterioration was taking place. The reports of medical officers of health on the school population did not indicate any deterioration in the health of the children of Scotland generally. They had kept a watchful eye on the vital statistics of the country. It was true that last year the pulmonary tuberculosis figures were higher than those of the year before, but they were lower than they had been for any year up to that time, lower than in 1921, 1922, 1923, 1924, and 1925. Non-pulmonary tuberculosis continued to fall and was lower last year than ever before. They all agreed as to the tremendous struggle through which industrial Scotland was passing and the Government were not blind to the situation. They recognised the urgent necessity to deal with it by legislation which would be laid before the House before the end of the present year. Dr. Shiels had said that the percentage of underfed and badly-fed children was too high and he (Major Elliot) agreed with him. They must continue to do their utmost by improving the school medical services and by tightening up regulations to make sure that the Education Act was carried out and that every child got sufficient nourishment to enable it to take advantage of education. There was no divergence of opinion between the Secretary of State and his advisers on the question of venereal disease. The report made it quite clear that in the opinion of the Secretary of State the time had not come to ask the House for further compulsory powers until they were sure that the powers already entrusted to the local authorities by the Government had been utilised to the full.

Dr. SHIELS said that the point he wished to make was that there was a divergence of opinion between the Scottish Board of Health and the English Ministry of Health and not between the Secretary for Scotland and his advisers.

Major ELLIOT said he could assure the hon. gentleman that the Secretary for Scotland was in no way inclined to defer to the opinion of the English Minister. He considered the matter on its merits in consultation with his technical advisers and in accordance with their advice he came to the conclusion mentioned in the report. The Scottish Board of Health were not flinching from drastic action to make sure that the milk-supplies were as pure as could reasonably be managed. In reply to Dr. Shiels's question as to the medical member of the Board of Health, everyone knew that Sir Leslie Mackenzie had now retired, and it was right that Parliament should take note of that fact and remember, with gratitude, the great work that he had done for the health of the people of Scotland—(general cheers)—during the many years that he had been entrusted with that duty. The reason that a new medical member had not yet been appointed to take his place was simply that the Bill for the Reorganisation of Offices in Scotland had not yet received the Royal Assent. As soon as that Bill became an Act of Parliament the Secretary for Scotland would proceed with the utmost expedition to make the new appointment. He had nothing further to report for the moment in regard to hospitals, but the proposals that Dr. Shiels had brought forward would be considered. He was not able to say that the shortage of hospital beds had been remedied, but an improvement was being effected almost monthly, with the provision of increased

hospital accommodation for the sick people of Scotland. Only a few weeks ago he had opened the new Northern Infirmary at Inverness where considerably increased medical facilities had been made available for the people in the northern districts. With regard to the report of the Departmental Committee on Maternal Mortality, the Board had done their utmost to bring up to date the system in Scotland in regard to the services for pregnant women. The Maternity Homes Act ensured that there was now a service available for 100 per cent. of the mothers of Scotland, a thing that could be said of very few other countries in the world. The Board had not succeeded in reducing the very high percentage of deaths from puerperal fever, but they were considering fresh steps for dealing with that matter. The service had been made available, however, and they would do their utmost, by administrative action, to secure that further institutional accommodation was made available for women in childbirth. In regard to tuberculosis there were fluctuations from year to year, but what they had to observe was the general trend of the figures and that gave them no reason to despair or to feel that any serious inroads were being made on the health of the people of Scotland. As regarded tuberculosis in the Island of Lewis they had done their utmost to deal with that matter. Sanatoria had been opened and there were three whole-time men and three medical officers of health and assistants working part time on that problem. It might be that they were dealing there with a hereditary resistance which was lower than the resistance on the mainland, or in those parts of the country which had been longer exposed to the infection of the disease. They were, however, at present engaged in investigations to see whether that was the case or not. The nine years during which the Scottish Board of Health had presided over public health matters in Scotland had been years of varying fortunes, but as regarded health, housing, and social conditions they showed a distinct improvement. If they could make as much progress in the next nine years he would be satisfied.

Mr. **Johnston** asked if the Under-Secretary could make some statement with reference to the practice carried on for some considerable time by one firm of importing inedible grease by the shipload from abroad and selling it to poor people as edible lard?

Major **Elliot** said that the Government took a serious and grave view of this matter. They felt that a definite offence had been going on. The local authorities upon whom the onus of prosecution fell had now the matter under consideration. The Government would not stand in the way of steps being taken, if they desired to take steps. The stock now under embargo in Glasgow would be dealt with as the order of the Court decided.

The vote was agreed to.

Ministry of Health Vote.

On Wednesday, August 1st, the House considered the Report of a vote of £13,774,025 for the salaries and expenses of the Ministry of Health.

Mr. **Lansbury** protested against the reduction which he said the Minister of Health was making in the grants for milk distribution, housing, and slum clearance, and poor-law relief.

Lieut.-Colonel **Fremantle** said that there had been presented to Parliament in the last two days a report from the Departmental Committee on Vaccination, which could not be taken into account so late in the session, but which must be referred to. Having enumerated the circumstances which led to the appointment of the Committee—certain objections to the practice of vaccination and certain doubts with regard to the necessity of its continuation on the present lines owing to the milder type of small-pox—he called attention to the danger represented by the large number of unvaccinated people which was increasing every year in proportion to the whole population, a circumstance which had an international aspect, because other countries held that vaccination was a very small price to pay for protection from a very alarming disease. Therefore action was required to be taken, and in the first instance a scientific committee was appointed to inquire into the nature of vaccination and into the various conditions which appertained to the operation of vaccination. That committee had presented a lengthy report which, from a scientific point of view, did great credit to its authors, and left the legislators very much in the same position as they were in originally from a practical point of view, for it showed that the position required further investigation on scientific lines.

Vaccination and Nervous Disorder.

There was one point which the report raised—it had been made a serious problem in the Press as well as in the House of Commons—and that was the occurrence in the period after vaccination of certain unfortunate cases of nervous disorder which had been stated by some hastily, and by others anxiously, as being possibly due to the operation of vaccination. This report dealt with those cases very thoroughly. They had to treat these exceptions in their proper light and proportion; and the report showed that they were a small number compared with the total number of vaccinations. The total number of cases with which the Committee dealt was 62, of which, unfortunately, a considerable number were fatal. They must recognise the seriousness of these facts; but when they were dealing with 314,000 primary vaccinations in one year 62 in all was a small number and they must not exaggerate its significance. The total number of deaths from vaccinia over a period of 15 years had only been 0·001 per 100 vaccinations. Still, these were facts which have to be faced and they who were such keen supporters of vaccination as essential to the community would be misleading the House if they did not face them. The report showed first of all that it was a curious thing that in the year 1924 the Committee could trace no cases whatever, although they searched most diligently through all the records of the results of vaccination, and those records were very complete. The Committee found some of these cases in 1922 and 1923. They found a close association between these cases and the epidemics of disease known as encephalitis lethargica and poliomyelitis. The conclusion that the Committee came to was that just as children suffering from scarlet fever, measles, and other ordinary ailments were more susceptible in a time of outbreak to poliomyelitis, so similarly those who had been vaccinated were liable to be attacked by these passing diseases in a time of epidemic. The Committee pointed out exactly the limits within which further observation was required, the points to which their sense of anxiety must be directed, and the directions in which in future they hoped to be able to find out exactly the nature of the trouble which had caused this symptom, which was entirely accidental both geographically—for it had occurred in Holland as well as in this country—and in years, and they might hope that they would not see them occur again.

The speaker looked forward to the improvement in vaccination administration that would follow its transference to the sanitary authorities, and deplored the conduct of those who, in defiance of the facts, tried to terrorise people on lines which every man who was sensible believed were scandalous exaggeration and malicious inventions.

Ministry of Health Estimates.

He would like to look shortly at the total estimates of the Ministry of Health. The total estimate for this year was £20,000,000, showing an increase of nearly £1,000,000 on last year, for excellent reasons. Of the £20,000,000 over half was due to housing, so that the public health side was under £10,000,000. The prevention of disease which was preventable had resulted, and was resulting, in an enormous improvement in the health and efficiency of the people as well as in their general habits. But the estimates for the Defence Forces amounted to £114,000,000. The real moral of the contrast between that large sum and the £10,000,000 spent on the prevention and cure of disease was that when there was a clear case made out for extra expenditure for the Ministry of Health there should be no question raised about it. If they could get general agreement on this on very side of the House he would suggest to those who, like himself, were keen on the prevention of disease and on improving the lot of suffering humanity, that they should be very careful what they supported and careful to avoid waste. There had been cases again and again where extra money has been asked really as an extra dole and not for the prevention of disease. They desired further provision to be made for the clearance of the slums. They must focus attention in the provision of housing for the very poor, and in order to do that it would be the duty of the State before long to remove the subsidy from the upper grades of houses, because the people who lived in those houses could look after themselves now.

Housing and Health Services.

Mr. **Harris** said the money which had been spent on housing and health services was most important, and it was more impressive when they remembered the immense improvement in public health during the last 15 or 20 years, largely due to schemes undertaken for that purpose. The various schemes which were initiated by the Government before the war had borne excellent fruit, and had justified the expenditure. In some boroughs, even in very crowded areas, the system of maternity and child welfare had had a remarkable effect on the death-rate. For instance, in Bethnal Green, the poorest neighbourhood in the whole of London, and the most overcrowded, they had reduced the infantile mortality to 57·7 per 1000. In that respect they had been able to take the prize for the best result in London. That figure compared with 59 per 1000 for London as a whole, and 69 per 1000 for England and Wales, including the rural and well-to-do districts. Their infant death-rate had shown a steady decline. In 1916 it was 106 per 1000. In 1918 129 per 1000. It then came down to 90 in 1922; next to 71, and this year it was 57. That reflected very great credit on the medical officer and the loyal servants who worked with him. It was not unreasonable to say that this improvement was largely due to the distribution of free milk. There had never been a better expenditure of public money than the giving away of milk through the health departments of the local authorities. In Bethnal Green milk was given to expectant mothers three months before confinement, to nursing mothers, and to children up to 3 years. One pint per day was given, and that was not enough to demoralise any woman or any child. Except for children between 3 months and 18 months no larger quantity was given; it was then at the maximum of 1½ pints, and in that case a medical certificate was required. He could not make out why the Minister of Health had singled out this expenditure on milk for his special veto. He now said that milk should not be given away to mothers or their children who were in receipt of poor-law relief, directly or indirectly. He required a special medical certificate before even a pint of milk could be obtained. That was most unfortunate. It might be said why should not these people buy the milk themselves? Unfortunately milk was not a popular diet; and they had to do a great deal of education in that direction. The Empire Marketing Board was spending thousands of pounds in putting up posters urging people to drink more milk. Not only was the distribution of milk valuable from an educational point of view, but it was most important at this very sensitive stage of a child's life.

Tuberculosis.

The complex problem of tuberculosis had racked the mind of every Minister of Health and of every local authority. The medical officer of health in Bethnal Green had given great attention to the subject. In connexion with the death-rate from tuberculosis a very serious phase had been pointed out to him. There had been a very heavy and rapid mortality among patients who had died within a year of notification. In 1917 the percentage of patients dying within a year of notification in Bethnal Green was 21·9, and in 1922 the percentage was 26·9. They had taken the trouble to follow up the cases. The reason for this alarming death-rate had been given to him by their very able medical officer as due to the diffidence among patients in informing the authorities that they were suffering from the disease. A conference of local authorities in London had pointed to the great success of the experiment at Papworth, where industrial training was correlated with treatment. The Minister of Health might well spend a little time inquiring into that matter, and take steps to encourage those suffering from the disease to notify the authorities earlier. All these health questions were, however, connected with the housing problem. One of the difficulties in dealing with tuberculosis was that when a man returned nearly cured, he had to go back to a two- or three-roomed tenement, and share the house with a family of five or six children. He was not going to underrate what the Ministry of Health or the local authorities had done, but there was a little danger in the optimism which said that most of the lee-way had now been made up. Whatever the Minister might do in the way of reducing the subsidy on the more expensive houses, he must on no account consider for a moment reducing the subsidy on houses which were wanted to meet the real and urgent need of the working classes.

Captain BOURNE said that there were on the registers of local authorities some 363,000 people suffering from tuberculosis, and of that number some 63,000 were treated in any one year in sanatoria. The average stay of a man in a sanatorium was some 150 days, and the cost per patient was 49*s.* 3½*d.* per week. That meant that the total cost of sanatoria treatment was between £4,000,000 and £5,000,000 per annum. If it were certain that that sum would really effect the cure of tuberculosis, he did not think anyone would grudge the money, but the Minister, when he was asked if he had statistics to show how many of the people who passed through sanatoria were cured had to admit that he had no reliable information on that subject. There had been in his constituency recently an effort to deal with some of these cases by means of the tuberculin treatment. While that method had been reported upon unfavourably, it had nevertheless been tried in some localities with very beneficial results. The tuberculin treatment had one advantage. It did not require isolation in a sanatorium, and a man who was undergoing it could go about his ordinary occupation. It was a very much cheaper form of treatment than sanatorium treatment, and although he spoke with great diffidence as a layman, he felt that anything which might possibly be helpful to people suffering from this disease ought to be investigated by the Ministry.

Mr. BRIANT raised the question of the conditions in the hop districts. He said that having seen these conditions for himself, and having studied the reports of the medical officers dealing with them, he did not hesitate to say that in a large part of these areas the conditions were absolutely disgusting and unfit for any human being.

Colonel APPLIN asked if the Committee on Maternal Mortality had reported, and if so, what was the nature of the report? Were they going on in the same old way allowing mothers to die when their lives might be saved? When the Committee had reported would the Minister consider giving the same information to the poor women as was given by private doctors to those who were better off? As long as that information was withheld, they would have this great mortality among mothers, and go on rearing a generation of young people unfit to come into the world by reason of their mothers being unfit to bear them.

The Welsh Board of Health.

Mr. JOHN protested against the Minister's action in reorganising the Welsh Board of Health. Under the new scheme he said they were to have no Board of Health in Wales, but instead they were to have three officers in Cardiff carrying out the work of civil servants under the direct instructions of Whitehall, with no provision whatever for joint action under a duly appointed chairman.

Mr. LLOYD GEORGE said he very much regretted that it should have been necessary to raise this question at all in the House. He had hoped after the representations made to the Minister, not merely by his political opponents but by the whole of his political friends in Wales, that he would have made this concession to the unanimous wish of the Welsh people without distinction of party or creed. He urged the Minister of Health to reconsider this matter.

The Minister's Reply.

Mr. CHAMBERLAIN (Minister of Health) said the Welsh Board of Health had never been a board in the ordinary sense of the word, because a board in the ordinary sense was an executive body, and the Welsh Board of Health had never been an executive body since it was set up. The Welsh Board had never had the powers of the Scottish Board of Health. This was purely an administrative matter. As to the question of economy, when he decided for reasons which appeared to him sufficient and satisfactory, that he could not appoint any existing member of the Board to be chairman, he had to consider whether he should bring in somebody else. The work of the Board of Health had not been executive, and it had found so little to do that on the average it had met only three times a year during the last nine years. All its work had been done by its members in their individual capacity. It had been extremely efficiently done, and he had not heard any complaints about it. To bring in a chairman, who would really have no functions, at a cost of £1600 a year would be a course in which he would not be justified. It was not his desire to bring into publicity anything in the nature of a reflection upon any member of the staff in Wales. He thought it necessary, in receiving the deputation on the subject, to say something about it, and he thought that they would consider it as a private matter between themselves and himself, but since it had been made public he would say here was a case, not of any dishonourable action on the part of anybody, but of a series of petty personal squabbles that had taken place in the office. He had disciplined and censured those who had been guilty of subordinating the public interest to their own personal prejudices and feelings. The matter was settled, but to put one of those who had been concerned in these internal differences into a position in which he could or might affect the promotion of others with whom the differences had arisen, did not seem to him a step which he could possibly take in the interest of the administration of public health.

Poor-law Relief.

Dealing with the question of poor-law relief, Mr. Chamberlain said they had not found any cases of starvation. There were many cases of hardship, but if it was really to be laid down by the Labour Party that those who were unable to support themselves were to be supported by the State on the same scale as those in full work, he said that it could not possibly be done. Complaint had been made about the reduction of the grant for milk. He much regretted that it should be necessary to make any reduction, but they had to bear in mind that the practice of local authorities as regarded the amount of milk given varied enormously. Some gave nothing at all, and in other areas the expenditure was up as much as £20 per 1000 of the population. All authorities could not be equally right in this matter. They had not laid down in a single case that this special form of assistance to nursing and expectant mothers was to be stopped. They had not forbidden any local authority to give milk or to give as much milk as it chose; all they had said was that they must limit the amount of the Exchequer grant, and the reduction was comparatively small. It was not a matter of policy on the part of the Ministry to reduce the amount of milk; if it had not been for economy he would not have done anything at all, but he would not like to admit that this economy was going to undo the work that had been done in the past in the preservation of infant life. What had happened was that having stated that the Exchequer grant in certain cases would have to be reduced, he had made certain suggestions which the local authorities could adopt if they desired to reduce their expenditure with the least possible disturbance to their existing practice.

Health Conditions in the Hop Fields: Sanatorium Treatment.

With regard to the hop fields the Ministry of Health had very little power beyond that of exhortation. What they needed in this matter was the education of public opinion. No doubt the conditions in the hop fields were very far from being what they should be, and he had done what he could to induce local authorities to adopt model by-laws, and to see that they were carried out. In the absence of further powers it was not possible for him to do more. Conditions were improving, though he agreed that there was much to be done. Captain Bourne had expressed some doubt as to whether they could be satisfied that the money spent on sanatorium treatment was justified by the results. They had not got figures from sanatoria all over the country which would show exactly what happened to people after they had been discharged, but some time ago they got from the Brompton Hospital Sanatorium particulars of between 3000 and 4000 patients who had been discharged. They showed in regard to the moderately advanced cases that after five years 57 per cent. of the males and 67 per cent. of the females were not only alive but apparently in good health; and that after ten years 38 per cent. of the males and nearly 50 per cent. of the females were also alive, and as far as he knew, in good health. That reassuring statement indicated that the money spent upon sanatoria was well spent; it prolonged the life of many people, and saved the lives of a good many others, and even where it was not able to do this, it did much to diminish the infection which otherwise might take place among the healthy population. In regard to housing, it was quite true that the progress made under the Rural Housing Act up to March, 1928, had been singularly disappointing, but in the three months since then progress had been very much faster. The number of dwellings in respect of which applications for assistance had been received, which was 1072 up to March, 1928, had increased to 1500 in the succeeding three months. In regard to housing in general, month after month not only the number of houses completed continued to go up, but also the number of houses under construction; and that number, which was only 48,000 last January, was to-day 59,000. He would be very much surprised if they did not get another 100,000 houses before the end of this year.

The vote was agreed to by 255 votes to 132.

THE LATE DR. HEYWOOD SMITH.—At the age of 90, Dr. Heywood Smith died at Chichester on July 25th. The son of Dr. Protheroe Smith, founder of the Hospital for Women, Soho-square, he was educated at Harrow and Christ Church, Oxford. His clinical training was obtained at St. George's Hospital, and on graduating in 1865 he held a house appointment there before taking up gynæcology as a specialty. He became M.R.C.P. Lond. in 1865, and proceeded to the M.D. degree at Oxford in 1870. Seven years later he published "Practical Gynæcology, a Handbook of the Diseases of Women," based on his experience on the staff of the British Lying-in Hospital and the Soho-square Hospital, to both of which he subsequently became senior physician. Other books and scientific writings followed, and Heywood Smith was one of the founders, and some years later president, of the British Gynæcological Society. On retirement from consultant practice in London he went to live at Hove, where he was living at the outbreak of the late war. Joining a veteran's corps, he was given medical charge of an air-raid station, and later did good work as civil medical officer to the Military Hospital at Chichester, where he finally established himself in retirement.

Dr. Heywood Smith, who was twice married, leaves a widow, two sons who are members of the medical profession, and a married daughter.

Medical News.

UNIVERSITY OF OXFORD.—At a congregation held on August 4th the degree of Bachelor of Medicine was conferred on T. L. Davies and A. J. Leslie-Spinks.

UNIVERSITY OF CAMBRIDGE.—Applications are invited for the Benn W. Levy Research Studentship, valued at £100 a year. They should be sent to Sir Gowland Hopkins at the Biochemical Department before August 14th.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At a meeting of the Council held on July 31st, Sir Berkeley Moynihan, the President, in the chair, diplomas of M.R.C.S. were conferred upon 158 candidates (130 men and 28 women) who have passed the requisite examinations and have complied with the by-laws of the College. These candidates are the same as those whose names were printed on p. 259 of our last issue, except that Nellie Brown (Westminster), David W. Currie (Leeds), Yatta Gimpelson (Royal Free and St. Mary's), Ralph H. Morley (Leeds), Bhavani Natarajan (Bombay), H. G. Nimbalker (Bombay and Middlesex), Margaret E. Peaker (King's Coll.), Edith J. L. Smith (Royal Free), G. N. Unnithan (Madras and Univ. Coll.), and Elsie E. Wright (Royal Free and St. Mary's) received their diplomas of Member at a previous meeting of the Royal College of Surgeons, and Thelma Shepherd (Royal Free) received her licence from the Royal College of Physicians on July 31st.

The Diploma of F.R.C.S. was conferred upon Herbert John Seddon (St. Bart.'s), who has passed the requisite examinations and has now attained the required age.

Licences in Dental Surgery were also conferred upon A. M. Bennett and H. A. Lewis, both of the Royal Dental Hospital.

Diploma in Tropical Medicine and Hygiene.—This diploma was conferred (jointly with the Royal College of Physicians) upon the following 33 candidates who have passed the requisite examinations:—

T. D. Amad, Maud C. Cairney, K. Cathiravelu, G. L. Chadha; S. S. Crosse, C. H. Devereux, J. P. M. Donnelly, N. M. Dotivala, Alice M. A. Downing, A. W. Duncan, H. A. Gilkes, M. A. E. Gohar, I. S. Gupta, N. Gupta, M. Jafar, H. C. Johnson, H. Kaitz, Mary Keith-Thompson, J. N. Leitch, K. R. Lundeberg, L. J. McGregor, C. D. Newman, Annie B. Price, E. L. Robert, A. N. Sharma, G. Singh, J. D. S. Thomas, R. F. Tredre, M. K. Tucker, K. H. Uttley, Kathleen A. Vernon, P. L. Whig, and E. R. Wide.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—As the result of the Final Examination of the Conjoint Board held in July, the following candidates were approved in the undermentioned subjects, but are not eligible for diplomas:—

Medicine.—S. Alstead, Liverpool; S. Annaswami, Madras and London; Nancy M. Badeley, Royal Free; S. W. Barber, St. Bart.'s; F. E. Camps, Guy's; Rochelle Churin, Royal Free; C. F. Cosin, Guy's; W. W. Craner, London; T. V. Crichlow, King's Coll.; H. W. D. Crook, Guy's; S. T. Crowther, Cardiff; T. M. Davie, Middlesex; E. L. Edmondson, Cambridge and London; C. N. Evans, St. Bart.'s; N. B. Fadia, Bombay and Middlesex; T. D. Finey and T. Fritz, London; Ruth C. Galletly, Royal Free; H. Gordon, Durham; I. Gordon, St. Bart.'s; E. Hacker, Leipzig and London; F. F. Hellier, Cambridge and Leeds; S. K. Jatar, Bombay and London; D. T. Jones and W. D. G. Jones, Guy's; S. Kin, King's Coll.; L. R. Lalwani, Bombay and London; Florence M. Lessing, Charing Cross; A. L. Light, Leeds; E. R. R. Mellon, Guy's; E. C. Murphy, London; D. A. Nicoll, King's Coll.; J. R. O'Neill, Leeds; C. R. L'E. Orme, Cambridge and King's Coll.; E. R. G. [illegible] ondon; P [illegible] Plummer [illegible]; G. Reah, [illegible]; C. Robinson, Cambridge and St. Bart.'s; S. A. Scorer and S. Shone, Guy's; H. Stark, St. Bart.'s; B. Stewart, Cambridge and Leeds; B. P. Sur, Calcutta; P. R. Thambugala, Calcutta and Middlesex; Ereenwin A. Utting, St. Mary's; and Sybil O. Williams, Royal Free.

Surgery.—Annie D. M. Adams, King's Coll.; A. G. Adrain, St. Mary's; H. H. Aitchison, Oxford and London; G. G. Allan, Univ. Coll.; S. W. K. Arundell, Middlesex; C. P. Bailey, Cambridge and St. George's; J. R. J. Beddard, St. Bart.'s; J. B. Blaikley, Guy's; R. M. Bolam, Cambridge and Durham; B. J. Bouche, Guy's; J. J. Boulle, London; A. M. Boyd, St. Bart.'s; G. H. Bradshaw, Cambridge and St. Bart.'s; F. E. Camps, Guy's; C. E. Caudwell, Westminster; M. A. Chamberlain, Manchester; F. Clifton, Cambridge and St. Thomas's; J. O. Clyde, Middlesex; S. M. Cohen, Cape and Guy's; Elizabeth Cooper, Royal Free; Florence K. Costello, Charing Cross; J. F. Crabtree, Manchester; D. F. L. Croft, St. Bart.'s; H. W. D. Crook, Guy's; S. H. Croot, Cambridge and Guy's; L. E. Daniel, St. Thomas's; T. M. Davie, Middlesex; C. C. Davis, Univ. Coll.; C. J. M. Dawkins, Cambridge and Middlesex; D. C. L. Derry, St. Thomas's; P. C. C. de Silva, King's Coll.;

R. Doyle, Liverpool; J. T. Dunkerley, St. Bart.'s; H. A. Eason, London; Dorothy E. Eglington, Royal Free; J. S. S. Fairley, Cambridge and Birmingham; W. R. Forrester Wood, Cambridge and St. Bart.'s; G. H. V. Froggatt, Sheffield; M. Gamboa, St. Bart.'s; Dorothea L. Gee, Royal Free; W. N. O. George, Univ. Coll.; R. Glanvill, Guy's; D. R. Griffith, St. Thomas's; C. C. Griffiths, Liverpool; Gwendoline E. Grove, St. Mary's; F. R. Gusterson, St. Thomas's; W. G. Harvey, St. Mary's; C. F. Howes, St. Thomas's; Esme I. Hyam, Univ. Coll.; P. G. S. Kennedy, London; R. W. Knowlton, Cambridge and Middlesex; L. W. A. Lankester, Cambridge and St. Thomas's; J. C. Lee, Cambridge and London; A. Levy, St. Thomas's; K. Lindberg, Middlesex; A. G. Lloyd, Durham; O. V. Lloyd-Davies, Middlesex; R. M. B. Lowis, St. Thomas's; T. K. S. Lyle, Cambridge and King's Coll.; R. G. Macbeth, Oxford and King's Coll.; A. L. McFarlane, King's Coll.; E. R. R. Mellon, Guy's; K. G. Milad, St. Mary's; W. B. Millar, Middlesex; V. L. Misso, King's Coll.; G. Morgan, St. Mary's; G. H. Morley, Middlesex; L. H. Mottet and T. Nallainathan, Univ. Coll.; G. Na Ranong, St. Thomas's; G. S. Nightingale, London; Edith G. Niven, Univ. Coll.; W. G. Oakley, Cambridge and St. Bart.'s; R. I. O'Farrell, Sheffield; E. Ogden, Univ. Coll.; A. J. Parer and Keren I. Parkes, King's Coll.; C. T. E. Parsons, St. Bart.'s; A. P. Petigura, Univ. Coll.; A. S. Philps and I. Preiskel, St. Bart.'s; S. R. C. Price, King's Coll.; F. S. C. Pritchard, Guy's; C. B. Prowse, Cambridge and St. Bart.'s; H. D. Pyke, Bristol; A. F. Quarmby, Birmingham; T. G. Reah, Cambridge and London; J. B. A. Reynolds, Cambridge and St. Bart.'s; R. A. C. Rice, St. Bart.'s; G. L. Robinson, Cambridge and London; Alice I. Roughton, Cambridge; E. L. Rubin, Liverpool; D. J. Sagor, Cape and London; C. J. Sanderson, St. Bart.'s; G. H. Sanderson, Cambridge and Univ. Coll.; R. V. Sanzgiri, Bombay and London; N. Schachnowitsch, Guy's; C. P. Scott, St. Thomas's; Mary Scouloudi, Univ. Coll.; J. E. Semple, Cambridge and St. Thomas's; W. H. H. Serasinghe, Middlesex; Mary E. Sharp, Univ. Coll.; S. Shone, Guy's; F. J. G. Slater, Cambridge and Durham: E. Somasekhar, Birmingham; A. Somerville, Sheffield; A. G. C. Taylor, St. Thomas's; J. M. Taylor, St. Bart.'s; L. Taylor, Sheffield; K. A. Thomas, Birmingham; Phyllis D. Towell, Royal Free; S. A. Underwood, St. Mary's; M. H. Wace, St. George's; R. G. L. Waller, Westminster; C. J. Waring, London; C. M. E. Warner, King's Coll.; J. Wasserzweig, London; Olive C. Watkin, Charing Cross; K. Watman, Middlesex; C. E. W. Wheaton, St. Thomas's; D. C. Williams, Cardiff; G. M. Willoughby, Middlesex; Winifred M. Wright, Royal Free; N. Yacoubian, Birmingham; and H. S. T. Young, Cambridge and St. Thomas's.

Midwifery.—Margaret Abernethy, Royal Free; D. A'Brook, Univ. Coll.; Annie D. M. Adams, King's Coll.; A. G. Adrain, St. Mary's; H. F. Apthorpe-Webb, Cambridge and St. Bart.'s; Lucy E. Arthur, Nancy M. Badeley, and Vera R. T. Baylis, Royal Free; R. C. Bennett, St. Bart.'s; W. L. M.Bigby and J. B. Blaikley, Guy's; A. D. D. Broughton, Cambridge and London; H. H. Brown, King's Coll.; M. K. Bryce, London; D. S. Chowdhary, Punjab; J. O. Clyde, Middlesex; G. C. Cochrane, London; S. C. S. Cooke, Middlesex; P. A. Cooper, Univ. Coll.; Florence K. Costello, Charing Cross; D. W. C. Cox, Guy's; T. V. Crichlow, King's Coll ; D. F. L. Croft and J. R. Crumbie, St. Bart.'s; T. J. Davies, Cardiff; C. C. Davis, Univ. Coll.; A. C. Dawes, King's Coll.; J. Donovan, Leeds; R. Doyle, Liverpool; W. J. D'Rosario, Guy's; M. A. A. El Gammal, Cairo; C. N. Evans and A. D. Everett, St. Bart.'s; D. Ezekial, Charing Cross; J. S. S. Fairley, Cambridge and Birmingham; W. B. Fiddian-Green, St. Mary's; C. H. Forsyth, London: R. H. Francis, Cambridge and St. Bart.'s; G. H. V. Froggatt, Sheffield; M. Frohlich, Brussels and Middlesex; R. L. Frost, Guy's; Ruth C. Galletly, Royal Free; B. C. Ghose, Durham; A. Gilpin, King's Coll.; R. Glanvill, Guy's; G. H. A. Graetz, Cambridge and St. Bart.'s; F. W. H. Grenier, London; D. R. Griffith, St. Thomas's: Bryneilen Griffiths and Rosentyl Griffiths, Cardiff; F. R. Gusterson, St. Thomas's; E. J. Hamp, London; Amy F. Hankins, Punjab and Royal Free; C. K. Haskard, Adelaide and London; Dorothy C. Hay, King's Coll.; J. Hopton, St Bart.'s; R. G. S. Howe, Univ. Coll.; Mary A. Hughes, Charing Cross; C. H. Johnson, Guy's; H. C. Johnson, Minnesota; W. H. P. Jonas, Oxford and St. Thomas's; Mary E. H. Jones, Cardiff; R. A. Jones, Cardiff; J. S

Mary L. R. Kennard, St. Mary's; P.

S. Kin, King's Coll.; R. W. Kn

Middlesex; M. Kokia, Westminster; L. W. A. Lankester, Cambridge and St. Thomas's; A. Levy, St. Thomas's; A. R. F. Lotaief, Durham: W. D. Lovelock-Jones, Cardiff; J. N. McArthur, Univ. Coll.; A. L. McFarlane, King's Coll.; Hilda M. C. Macmahon Garry, Liverpool; J. K. Marshall, Oxford and Guy's: S. N. Mathur, Lucknow; R. A. Maynard, Cambridge and St. Thomas's; W. B. Millar, Middlesex; G. Stuart, St. Mary's; B. P. Sur, Calcutta; I. Taylor, King's Coll.; C. D. Trimble, Birmingham; S. A. Underwood, St. Mary's; Bertha D. Upton-Jones, Royal Free; M. H. Wace, St. George's: R. Warnecke, J. Wasserzweig, and S. N. Wasti, London: Olive C. Watkin, Charing Cross; L. H. Wharton, Bristol: C. E. W. Wheaton, St. Thomas's; J. S. Whiting, Cambridge and St. Bart.'s; A. W. Williams, Cambridge and Westminster; L. V. Williams, St. Bart.'s; G. M. Willoughby, Middlesex; W. R. Winterton, Cambridge and Middlesex; F. G. Wood-Smith, Cambridge and St. Bart.'s: M. G. Woolff, St. Thomas's; N. Yacoubian, Birmingham; and H. M. Yardley and H. S. T. Young, Cambridge and St. Thomas's.

Pathology (New Regulations).—Doris Ascough, Manchester; J. R. J. Beddard, St. Bart.'s; H. J. W. Bergh, St. George's; C. E. Caudwell, Westminster; S. C. S. Cooke, Middlesex: E. F. Hunt, St. George's; H. G. McGregor, Guy's; A. H. Nelson, Charing Cross; T. B. Pitts, Guy's; and J. E. C. Sayers, St. Thomas's.

ST. BARTHOLOMEW'S HOSPITAL AND COLLEGE.—The Old Students' annual dinner is to be held on Monday, Oct. 1st, with Sir D'Arcy Power presiding.

ROYAL COLLEGE OF SURGEONS IN IRELAND.—Honorary Fellowship of the College has been conferred on Dr. Hugh Hampton Young, clinical professor of urology in Johns Hopkins University, Baltimore.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—The College will be closed for the summer vacation from Monday, August 13th, to Saturday, Sept. 15th, both days inclusive.

ST. MARY'S HOSPITAL ANNUAL DINNER.—The past and present students' annual dinner of St. Mary's Hospital will be held on Friday, Oct. 5th, at 7.30 P.M., at the Trocadero Restaurant, with Dr. E. G. Moon in the chair. The hon. secretary is Dr. A. Hope Gosse.

EXTENSION OF PAIGNTON HOSPITAL.—Sir Mortimer Singer has laid the foundation-stone of an extension of Paignton and District Hospital. The addition provides 20 more beds, a new private ward, a new out-patients' department, and an enlarged operating theatre.

BY a vote of 25 to 12 Bournemouth Borough Council decided on July 31st to sanction the use of unclaimed bodies at the Park Prewett Mental Hospital for anatomical examination at the University of Oxford. The request came from the Ministry of Health through the medical superintendent of the hospital.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL.—Princess Louise, Duchess of Argyll, recently laid the foundation-stone of a wing named after her. It will consist of five floors, the lowest being occupied by a large out-patient department. Each of the other floors will have a ward of 15 beds with operating theatre and the necessary adjuncts. The two upper floors will not be completed, in accordance with the policy of the institution, until the money is in hand. The total cost will be £52,000, of which £28,000 is now available. Princess Louise stated that there is a waiting-list of over 2000 cases needing operative treatment.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—On August 13th begins a two weeks' course at the Infants Hospital, starting daily at 2 P.M. and consisting of lectures and demonstrations, together with special visits to other baby welfare centres. On August 27th the Queen Mary's Hospital will begin a two weeks' course in medicine, surgery, and the specialties. In the mornings there will be lectures and demonstrations, while in the afternoons there will be a choice of operations or medical, surgical, or special clinics, followed by a lecture after tea. Special courses in September have been provided as follows: Psychological medicine at Bethlem Royal Hospital; medicine, surgery, and specialties at Westminster Hospital; children at the Queen's Hospital; electrotherapy at the Royal Free Hospital; ophthalmology at the Royal Eye Hospital; orthopædics at the Royal National Orthopædic Hospital. In October the Fellowship will again arrange weekly clinical demonstrations in medicine, in surgery, and in ophthalmology, also a special series at the Wellcome Museum of Medical Science, and a series of lectures on gynæcology, children's diseases, and minor surgery. Detailed syllabuses and other information may be had from the Secretary of the Fellowship at 1, Wimpole-street, London, W. 1.

A COURSE of study on Digestive Pathology will be held at the Hospital de la Santa Cruz at Barcelona from Oct. 5th to Dec. 10th under the direction of Prof. F. Gallart y Monés. Application for enrolment should be made to the *Administración del Hospital de la Santa Cruz*, Depositaría, Barcelona.

PRIVATE PATIENTS AT NORWICH.—Since the Private Patients' Department of the Norfolk and Norwich Hospital was opened in April last, 70 patients have been admitted, and recently not only has every bed been occupied, but there is already a small waiting-list. Payment of 30*s.* a year ensures treatment for a married man and his wife, with children under 16 whose income does not exceed £550 per annum; for a man and his wife, with no young children, whose income does not exceed £450, and for a single person with not more than £350 per annum.

CHRISTMAS MEDICAL TOUR ON THE CÔTE D'AZUR.—For the fifth year in succession a Voyage Médical International is being planned after Christmas to places of medical interest on the Mediterranean littoral. The rendezvous is Marseilles on Wednesday, Dec. 26th, to be followed by a day spent in visiting that port and another at Toulon. Then on successive days will be reached Hyères, St. Raphael, Cannes, Le Cannet, Grasse, Juan-les-Pins, Antibes, Nice, Menton, Monaco, Beaulieu, with opportunity for visiting the Roman citadel of La Turbie, the prehistoric grottoes of Grimaldi, the laboratory of Dr. Voronoff, the observatory of Nice, and other objects of scientific interest. Demonstrations and historical lectures will be given. For further information apply to the President of the Société Médicale du Littoral Méditerranéen, Dr. M. Faure, 24, rue Verdi, Nice, A.M., France.

THE LATE DR. C. H. NEWBY.—Dr. Charles Henry Newby, who died at his home in Ilfracombe on July 11th, was born at Ryde, Isle of Wight, in 1849, and was educated at the Merchant Taylors' School. After qualifying as M.R.C.S. in 1873 he held house appointments at St. Thomas's Hospital, and became surgical registrar there. As surgeon for the National Aid Society he was decorated with the Fourth Order of the Turkish Medjidie after the Turco-Serbian War of 1876. In 1880 he took the diploma of F.R.C.S. Eng. and in 1885 joined the expedition sent to Khartoum for the relief of General Gordon. For his part in this campaign he received the English war medal and the Khedival Star. In the following year he saw service in the Turco-Bulgarian War, gaining the Red Cross of Serbia and the Order of St. Save. Settling in practice at Southsea he became medical officer for out-patients at the Royal Portsmouth Hospital. On retirement to Ilfracombe in 1904 he associated himself with the work of the Tyrrell Cottage Hospital, and acted as its treasurer for many years. He leaves a widow and two daughters.

RATING OF LANCASHIRE HOSPITALS.—A conference to decide the basis of assessment for various buildings of a public character has been held at Manchester between the County Valuation Committee and the Rating Authorities and Assessment Committees of Lancashire. Seventeen assessment committees and 119 rating authorities were represented. It was decided that voluntary hospitals should be assessed, gross, at from 20*s.* to 30*s.* per bed, including the beds of the staff, with additions for facilities for outdoor and special treatment, and paying patients. Rate-maintained hospitals are to be assessed, gross, at from £2 to £4 per bed of patients and staff, likewise with additions for outdoor and special treatment. This scale is to be applied also to mental hospitals, sanatoriums, and similar institutions, with additions where they are justified on account of recreation and other purposes.

THE LATE DR. D. P. COOPER.—The death is reported from Surat, at the age of 93, of Dr. Dosabhoy Pestonji Cooper, a pioneer of Western medicine in the Bombay Presidency. Educated at the Grant Medical College, Bombay, where he graduated in 1863, he was two years later appointed medical officer to the Parekh Dispensary at Surat, where he settled in practice. He was first president of the Surat Medical Association founded in 1886 and in the following year was appointed Khan Bahadur for his public services. In 1899 he was awarded a certificate of merit for his work during the plague epidemic, and for a time he acted as civil surgeon for the city. For nearly 50 years, from 1867, he served the municipality as councillor and he was an honorary magistrate. Among other distinctions conferred upon Dr. Cooper was the Fellowship of the University of Bombay, and he was appointed honorary assistant surgeon to the Viceroy in 1885, receiving the Kaiser-i-Hind silver medal. He was a staunch and active Freemason for over half a century. Of his sons two are members of the medical profession.

KING GEORGE HOSPITAL.—In the recent special distribution of the Wells legacies, King Edward's Hospital Fund for London set aside a grant of £10,000 towards the building fund of King George Hospital, subject to conditions to be agreed. The Fund has been informed that steps will shortly be taken to invite the support of the charitable public for the establishment of the hospital. The scheme, as submitted to the King's Fund, contemplates the provision of additional hospital accommodation for the parts of Essex immediately to the East of London, including the area for which such accommodation is particularly needed owing to the development of post-war housing. The King's Fund proposes to summon a conference with a view to facilitating the execution of the scheme.

THE LATE DR. J. W. MELVILLE.—At the early age of 24 Dr. John Walter Melville died at Liverpool on July 22nd after an operation for appendicitis. Educated at the Barrow-in-Furness secondary school, and at the University of Liverpool, he qualified as a medical practitioner and as a dental surgeon in 1926, and graduated as M.B. in the following year. Last October he was appointed tutor in dental surgery in the University of Leeds, but it was his intention to take up general surgical work, and he resigned this appointment in order to take up the post of resident house surgeon at the Royal Southern Hospital, Liverpool, which he held at the time of his death. The funeral took place at Rampside, near Barrow, on July 25th.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.
Special two weeks Course in Infant's Diseases at the Infants Hospital, Vincent-square, Westminster.

MONDAY, August 13th.—2 to 3 P.M., Dr. W. E. Robinson: Cases of Malnutrition and Intestinal Toxæmia. 3 to 3.45 P.M., Dr. Eric Pritchard: Lecture-Demonstration. Caloric Values. 4 to 5 P.M., Dr. Eric Pritchard: Lecture, General Principles of Nutrition.

TUESDAY.—2 to 3.45 P.M., Dr. Eric Pritchard: Feeding Cases. 4 to 5 P.M., Dr. M. Maizels. Pathological Demonstration. Cerebro-spinal Fluid.

WEDNESDAY.—2 to 3 P.M., Dr. W. E. Robinson: Cases of Rickets and Scurvy. 3 to 3.45 P.M., Dr. Eric Pritchard: Lecture-Demonstration. Modification of Cow's Milk. 4 to 5 P.M., Dr. Elizabeth Karn: Lecture-Demonstration. Ultra-Violet Rays.

THURSDAY.—2 to 3.45 P.M., Dr. Eric Pritchard: Cases of Tuberculosis. 4 to 5 P.M., Dr. W. E. Robinson: Lecture, Respiratory Diseases in Infancy.

FRIDAY.—2 to 3 P.M., Dr. Eric Pritchard: Cases. 3 to 3.45 P.M., Dr. Eric Pritchard. Lecture-Demonstration. Diet of Children. 4 to 5 P.M., Mr. D. Levi: Lecture, Pyloric Stenosis.

SATURDAY.—2 P.M., Visit to Home for Blind Babies, Chorley Wood; and to the Infants Hospital Convalescent Home, Burnham Beeches.

SUNDAY.—11 A.M., Visit to V.D. Centre, Thavies Inn, Holborn-circus. Prophylactic Treatment of Syphilis in Infants.

Appointments.

CAMPBELL, W. S. H., M.B., Ch.B. Edin., D.P.H., has been appointed Chief Medical Officer of Health to the Lindsey (Lincs.) County Council.

HOARE, E. F., M.D., Ch.B. Liverp., Coroner for East Sussex, in succession to the late Dr. W. A. Dow.

MACDONALD, A. D., M.B., Ch.B. Edin., Reader in Materia Medica and Therapeutics, University of Manchester.

SAUNDERS, J. C., M.B., B.Ch., D.P.H. N.U.I., Superintendent Medical Officer of Health and Tuberculosis Officer for Cork-le-Boro.

Certifying Surgeons under the Factory and Workshop Acts: BRAND, W. H. E., F.R.C.S. Edin. (Banchory, Kincardine); and LEWIS, W. B. A., M.B., B.Ch. Camb. (Oswestry, Salop).

Vacancies.

For further information refer to the advertisement columns.

Aberystwyth, Aberystwyth Infirmary and Cardiganshire General Hospital.—H.S. £200.

Ayr County Hospital.—Jun. H.S. At rate of £80.

Barry Accident and Surgical Hospital.—H.S. At rate of £200.

Bath, Royal United Hospital.—Asst. H.S. £100. Also H.S. and H.P. Each £120.
Bedford County Hospital.—H.S., also Asst. H.S. At rate of £175 and £130 respectively.
Birmingham, General Hospital.—Med. Reg. and Res. M.O. £155.
Bolton, Townleys Hospital, Farnworth.—Second Asst. M.O. £225.
Bootle, Bootle Borough Hospital, Derby-road.—Sen. M.O. Also 2 Jun. M.O.'s. Each at rate of £150 and £125 respectively.
Bradford, Municipal General Hospital (St. Luke's).—H.P.'s and H.S.'s. Each at rate of £200.
Canterbury, Kent County Mental Hospital, Chartham.—Jun. 4th Asst. M.O. £300.
Canterbury, Kent and Canterbury Hospital.—Hon. Surg. to Ear, Nose and Throat Department. Also Third Res. M.O. At rate of £125.
Cardiff, Prince of Wales' Hospital.—H.S. £100.
Carmarthen, Joint Counties Mental Hospital.—Jun. Asst. M.O. £300.
Dreadnought Hospital, Greenwich.—Surg. to Out-patients.
East London Hospital for Children and Dispensary for Women, Shadwell, E.—H.P. At rate of £125.
Glasgow, University of.—Gardiner Chair of Physiological Chemistry.
Ilkeston, Borough of.—M.O.H. and School M.O. £800.
Leeds, City of.—Asst. M.O.H. for Maternity and Child Welfare. £800.
Leicester, City Education Committee.—Asst. School M.O. £600.
Maidstone, Kent County Mental Hospital.—Med. Supt. £1000.
Manchester Royal Infirmary.—Jun. H.S. At rate of £100. Also Hon. Asst. Radiologist and Electro-Therapeutist.
Market Drayton, Salop, Cheshire Joint Sanatorium.—Asst. M.O. £250.
Newcastle-upon-Tyne, Wingrove-road, Westgate-road.—Res. M.O. £250.
Nottingham Children's Hospital.—Res. H.P. At rate of £150.
Nottingham City.—M.O.H. £1440.
Oldham Royal Infirmary.—H.S. At rate of £175.
Plymouth, Homœopathic and General Hospital.—H.S. At rate of £100.
Reading, Royal Berkshire Hospital.—3rd H.S. £150.
Rotherham, Rotherham Hospital.—H.P. £180.
Royal Northern Hospital, Holloway, N.—H.S. At rate of £70.
Swansea General and Eye Hospital.—Hon. Phy. Also Sen. Res. O. £250.
West [illegible]h and District General Hospital.—[illegible] H.S. Each at rate of £200.
West [illegible] 155, Marylebone-road, N.W.—Jun. Non-Res. H.S. At rate of £100.
West London Hospital, Hammersmith-road, W.—Non-Res. Cas. O. £5 5s. per week.
Winchester, Royal Hampshire County Hospital.—Hon. Physician.

Births, Marriages, and Deaths.

BIRTHS.

JEPPS.—On July 27th, at St. Quentin, Broadstairs, the wife of Dr. J. W. W. Jepps, of a son.

LINELL.—On July 22nd at Wellesley Hospital, Toronto, to Frances, wife of Dr. Eric A. Linell—a daughter.

LLOYD.—On August 1st, at 29, Bramham-gardens, S.W., to Olive, wife of W. Ernest Lloyd, M.D., M.R.C.P.—a son.

MARRIAGES.

DAGGETT—SIMPSON.—On July 30th at St. Martin-in-the-Fields, London, William Ingledew Daggett, M.A., M.B. Camb., F.R.C.S. Eng., to Eileen Hilda, youngest daughter of Colonel and Mrs. Simpson, of Fowey, Cornwall.

LEWIS—IRVINE.—On July 31st, at All Saints' Church, Panarth, Kingsley Wassell Lewis, M.B., B.S., M.R.C.S., L.R.C.P., to Florence Henrietta, third daughter of the late Henry O. Irvine, of Southerndown, and of Mrs. Irvine, of Salisbury-avenue, Panarth.

MACINNES—MASTERMAN.—On August 1st, at St. Giles's Church, Camberwell, the Rev. Angus Campbell Macinnes, to Florence Isabella Joy Masterman M.B., B.S. Lond.

MARTIN—GARFIT.—On July 31st, at Partney Church, Lincolnshire, Peter Henry Martin, B.M., B.Ch., M.R.C.P., to Phyllis Mary Garfit, third daughter of the late Bartholomew Claypon Garfit and of Mrs. Garfit, of Dalby Hall, Spilsby.

MUNRO—LOWTHER BOUCH.—On August 2nd, at Ackworth Parish Church, James Gibson Munro, M.B., Ch.B., of Kimberley, Nottingham, to Lilias Anne, eldest daughter of J. Lowther Bouch, Rector of Ackworth.

SCHOLEFIELD—DEAN.—On July 28th, at Caerphilly, South Wales, Bernard Graham Scholefield, D.M., F.R.C.S., to Queenie, younger daughter of Mr. and Mrs. C. H. Dean, of Berwyn, Caerphilly, South Wales.

DEATHS.

BURT.—On August 5th, at Langdale, Salisbury-avenue, Harpenden, William Burt, M.B., B.S. Lond., late of Finchley.

CARROLL.—On August 1st, at 3, Artillery-mansions, Woolwich, Louis Ely Reginald Carroll, M.R.C.S., L.R.C.P.

HENTSCH.—On August 1st, George Frederick Hentsch, L.R.C.P., M.R.C.S.

MARSH.—On August 1st, at Mosley House, Boothstown, James Marsh, M.B., C.M., late Medical Officer of Health, Atherton.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE RED CROSS IN TIME OF PEACE.

AFTER ten years of peace it is well to be reminded that this generation can never lose the scars of war; the work of the Red Cross emphasises facts which most of us find it easy to forget. The eighth report of the joint council of the Hospital of St. John of Jerusalem and the British Red Cross Society, which covers only nine months, shows that their excellent work for ex-Service men has continued actively. During this period 308 tuberculous officers were helped, bringing the total since 1914 to 17,798. As time goes by, applicants find it increasingly difficult to satisfy the Ministry of Pensions that their disability is due to war service, and the Red Cross gives the necessary assistance while a case is pending. Other officers have finished their course at a sanatorium, but need financial aid in securing specialties of diet while on home treatment. Others, again, are helped with travelling expenses to Switzerland or the Riviera. The hospital at Brighton was filled the whole time, and some of the patients were very seriously ill when admitted.

An important activity of the fund is the provision of materials and training in various handicrafts for pensioners who cannot train in the hospital workshops. Approximately 1000 men were helped in this way during the nine months. The industries taught are increasingly popular and the medical superintendents speak highly of the great benefit conferred. Ex-Service men in Ministry of Pensions' hospitals are sent Christmas presents of the value of 5s. each, and over 2000 of them were cheered in this way on Christmas Day, 1927. About 13,000 men were taken out for drives or rides, or transported to entertainments. Although a number of Ministry hospitals have been closed, the diminution in the number of men still under treatment is not very great; they are simply being concentrated in larger institutions. The Emergency Help Committee, founded to give temporary emergency relief to ex-Service men and their widows and dependents, has also continued active. Many men, handicapped by disability, have been rendered self-supporting. 18,353 new cases were assisted during 1927, but no fewer than 12,187 applications were refused on the ground that there was no definite end in view or that they were ineligible or undeserving. One activity of this committee is to provide motor attachments to invalid chairs, and already 357 heavily disabled pensioners have thus been enabled to travel about without fatigue. The Games and Comforts Fund made 238 grants for wireless and cinema apparatus, musical instruments, cigarettes, clothing, bagatelle and billiard tables, gramophones, and all kinds of outdoor and indoor games. The Spero Firewood Factory for tuberculous ex-soldiers had to be closed down, but was fortunately able to reopen as the result of a special grant. From the medical point of view the factory proved most successful. The experiment of Scio House—a comfortable, "homely" institution for ex-officers suffering from advanced tuberculosis—has proved an unqualified success.

No less important than this continuing war work are the activities of the Red Cross Home Service Ambulance Committee, whose vehicles carry a steadily increasing number of sufferers every year. Modern methods of diagnosis and treatment depend so much on immovable mechanical apparatus that the mobility of the sick is becoming really important. In 1920, each of 273 ambulances carried an average of 125·6 patients. In 1927 the average had increased to 267·7. First-aid boxes are being set up on main roads, and all over the country members of the Order and Society spend their week-ends and holidays on the roads, armed with splints, bandages, and dressings. Considering the fact that 138,774 accidents, involving death or injury, took place on the roads of the United Kingdom in 1926, the Council feels justified in appealing for more voluntary workers for this service. The mobile X ray service is being *increasingly* used and a second car has been equipped.

THE INTERNATIONAL HANDBOOK OF CHILD CARE AND PROTECTION.[1]

SINCE the first edition of this remarkable book appeared in 1924 200 pages have been added to its bulk and 3*s.* to its price. The somewhat inadequate "International Who's Who" has disappeared, its place being taken by a useful bibliography, and a much fuller index than heretofore enables the inquirer to find more easily the particular information he desires. Mr. Edward Fuller, who has carried out the arduous task of compiling a record dealing with 300 countries or political units, excuses himself for inequalities of presentation, pointing out that the details are supplied in various forms and a dozen languages, that some replies are received two years after sending out the questions—though the Governor of Guadeloupe is the only one bold enough to state that his statistics are authoritative for five years—while there is no sort of agreement among English-speaking people as to what they mean by "child welfare." Many surprises are met with in turning over the pages of this volume; for instance, that child welfare work has been carried on in Afghanistan since 1910, that both infant vaccination and education are compulsory in the Bahamas but neither in Barbados, that abortion is legal in Russia, that no less than 2,300,000 children in Germany are cared for by public and private charity, and that the infant mortality-rate in the Republic of Cuba is only 31 per 1000, falling to 20 in the city of Havana. Mr. Fuller says that his purpose is to place his readers "in possession of information which is not available in any other single volume or in any one country (and in many instances not at all outside official documents not always published) leaving each reader to marshal the facts as he will and to make his own comparisons." The book is admirably suited to fulfil this aim.

NITRITES IN SEA-SICKNESS.

Dr. J. F. Pearcy and Dr. D. B. Hayden, of Chicago,[1] believe that sea-sickness is mostly, if not entirely, due to over-stimulation of the vestibule. In studying the effects of blood pressure on labyrinthine function, they found that sodium nitrite, by lowering the blood pressure, markedly diminished nystagmus and past-pointing after rotation. When Dr. Hayden found himself among 16 sea-sick people on an Atlantic boat he naturally tried sodium nitrite. Eight of them were left to suffer and remained ill for an average of two days, despite injections of epinephrine hydrochloride. The eight who took grs. 3–5 of sodium nitrite every two hours were all comfortably eating on deck in an average of four hours, and did not relapse. Dr. A. Sellheim,[2] of Leningrad, has treated 20 cases with a drop of a 1 per cent. solution of nitroglycerine in water or two drops of a ½ per cent. solution on the tongue. All the patients recovered. There seems to be scope for the trial of these methods, but vigorous reduction of blood pressure is not without its dangers, and the nitrites and nitroglycerine are drugs to be handled with considerable caution. If their effect should prove to be mainly psychological some milder vehicle for faith would be preferable.

A HANDY CARD-INDEX CLIP.

Messrs. Cooper, Dennison, and Walkden, Ltd. (7 and 9, St. Bride-street, London, E.C. 4), have sent us specimens of the "transparent" card hinge, invented by Dr. J. M. F. Whitby, to which attention has already been called in our columns. The device consists of two circular discs of transparent linen stitched together down the centre and having their opposing surfaces gummed. They are adapted for use in any card-index cabinet, as one record card can be quickly attached to another which has been filled up, thus making up a book of cards. The salient points about the hinges which are already in use by insurance practitioners and others are their cheapness, ease of manipulation, saving of labour, and readiness to hand. The price is 1*s.* per box of 100, 7*s.* 6*d.* per box of 1000, postage extra.

ANIMALS AND REASON.[3]

Dr. Warden, who is assistant professor of psychology in the Animal Laboratory, Columbia University, has written a brief account of how man throughout the ages has interpreted what he has been able to learn of animal life. The story of science in its larger meaning, he points out, is the story of an unceasing attempt on the part of man to understand his own place in the natural order of things, and he surveys accordingly the facts that have emerged and the opinions that have been expressed along the lines of comparative pyschology indicating the rise of this branch of learning to an exact science. Noting that the space made available by the format of the series has only permitted the briefest attempt at an historical survey, his hope is that he may be able to place modern movements in proper historical perspective, and his object is attained. He deals with his subject under five headings, ancient animal lore, the Greek influence, the psychology of the Early and Middle Ages (the period covering the decline of the Roman Empire and the rise of Christianity which terminates with the sixteenth century), the period between the opening of that century and the establishment of Darwinian principles, and, finally, with the experimental methods which have brought comparative psychology to-day into an exact science. He regards Darwin as the founder of moderr [illegible] as when the doctrine of evolution had [illegible] "a measure of sanity in interpreting a [illegible] ie apparent, but in a technical closing section—the longest—he shows where experimental methods have conducted the leaders of the science. A very interesting little book.

NEW PREPARATIONS

Citobaryum.—This [illegible] Napp, Ltd., 3 and 4, [illegible] the large modern deve [illegible] meal has become a fa [illegible] sulphate is largely replacing bismuth carbonate as an aid for outlining the alimentary tract. The manufacturers have put the preparation on the market, the insoluble sulphate for X ray diagnosis, in a palatable and convenient form, and it is supplied in packets of 150 g., this quantity being estimated as needed for one examination. Full directions for use are supplied and stress is laid upon the fact that the granular external character of the salt disappears if the directions are followed leaving a meal free from objectionable sedimentation.

Shadoform is a special preparation for the ready production of a liquid barium meal issued by the British Drug Houses, Ltd., Graham-street, City-road, N. 1. Its advantages lie in the ease with which the meal can be prepared—it requires merely to be mixed with water—in the thin cream-like consistency of the meal and the complete absence of lumps or grit, in its palatability and opacity, and in the remarkably long time the solid matter remains in suspension. Shadoform is issued in packages of four sealed boxes, each of which contains the equivalent of 4 oz. of chemically pure sulphate of barium.

SIR MORELL MACKENZIE'S BIRTHPLACE.

To the Editor of THE LANCET.

SIR,—Some of your readers interested in medical history who happen to be in the neighbourhood of Leytonstone, London, may like to glance at the house where Sir Morell Mackenzie was born in July, 1837. The old house, with the worn stone steps and the shop in front, is now empty and dilapidated, and if not shortly pulled down may be painted by a new tenant out of knowledge. The house stands at the corner of Browning-road, Leytonstone, which is a small antiquated road turning off the main road, quite close to the "Green Man" Inn, which is advertised as a stopping place by all the tramcars and buses. In all the obituaries I have read no mention is made of the exact spot. The visitor will find a tablet let into the side of the house about 20 ft. from the ground, which commemorates the fact.

I am, Sir, yours faithfully,

OBSERVER.

London, August 7th, 1928.

ACTIVE TREATMENT AFTER ELECTRICAL TRAUMA.

ELECTRICAL injuries, perhaps more than any other, call for conservative treatment as a general rule. The reason for this is the tendency of the affected tissues to necrosis and hæmorrhage. Nevertheless, as Prof. S. Jellinek[1] has recently pointed out, active measures are called for by certain definite indications. Rupture of vessels may give trouble in the third or fourth weeks, and however carefully ligatures are applied they are always liable to cut through the altered vascular wall. Cerebral œdema calls for lumbar puncture, an operation which this authority recommends as a first-aid measure in all electrical accidents. Amputation and surgical intervention, usually with the object of removing damaged tissues, should be rigidly avoided except when there is disturbance of the general health and its cause is undoubtedly the local lesion. Prof. Jellinek insists strenuously that the ordinary rules of pathology frequently do not apply here, and that hundreds of these operations are performed unnecessarily. A fourth indication is the division of nerves by wire or metallic edges. Otherwise the more conservative the treatment of electrical injury the better.

CLOSING OF WAR HOSPITALS.—Two of the great Birmingham War Hospitals, Uffculme and Sorrento, were closed last week, being no longer required for their original purpose. From 1919 to 1923 Uffculme was devoted solely to orthopædic and limb cases; since then it has been used for general surgical and medical cases, and as a centre for the supply and repair of artificial limbs. Sorrento, which was used mainly for paraplegic cases, will now become a maternity home under the City Health Committee.

A Contribution
TO THE STUDY OF
CHOREA.
THE SYMPTOMS WHICH RESULT FROM INJURY OF THE CORPUS LUYSII.

By J. PURDON MARTIN, M.D. Belf.,
M.R.C.P. Lond.,
ASSISTANT PHYSICIAN TO THE NATIONAL HOSPITAL FOR NERVOUS DISEASES, QUEEN-SQUARE; AND PHYSICIAN TO THE SEAMEN'S HOSPITAL, GREENWICH.

THE corpus Luysii, corpus subthalamicum or body of Luys, is an almond-shaped ganglion situated just below the optic thalamus (see Fig. 1); it lies immediately internal to the fibres of the pyramidal tract as they pass down from the internal capsule to the pes of the cerebral peduncle. Medial to it is the red nucleus and that complicated space known as Forel's field; below it is the substantia nigra. Its greatest length measures about 1·2 cm. The fibres which enter it come almost entirely from the lenticular nucleus, passing in considerable numbers across and around the internal capsule; of its efferent fibres some, as will be shown, descend into the mid-brain behind the substantia nigra, and a few cross under the floor of the third ventricle to the corpus Luysii of the other side. The knowledge of its connexions is still very incomplete. Of its functions I think it is fair to say that there has hitherto been no knowledge, although a few observers have drawn tentative conclusions from isolated cases.

In a paper read at the combined meeting of the American Neurological Association and the Neurological Section of the Royal Society of Medicine, held in London last July, a description was given of the following case, in which the only lesion found post mortem to which the symptoms observed during life could be ascribed was a small hæmorrhage destroying and practically limited to the body of Luys of the left side of the brain.

History of the Case.

The patient was admitted to the Seaman's Hospital under my care on Feb. 12th, 1927, and subsequently transferred to the National Hospital, Queen-square. He was a man of large build, aged 62, formerly a seaman, and latterly employed as a night watchman on board ships in dock. He had had no previous illnesses, but at the time he came under observation had very atheromatous arteries, his systolic blood pressure was 190 mm. Hg, and he had a considerably enlarged heart; the Wassermann reaction in his blood was positive.

Except for frequent headaches during the preceding six months, he had been well until Feb. 8th. On that morning, about 8 o'clock, just after arriving home from his night's work, he felt giddy, staggered, and had a severe pain in the right side of his body. He sat down for a little, then felt better, had a meal and went to bed as usual. When he woke up at 4 o'clock in the afternoon he tried to take a cup of tea sitting up in bed, but his right hand "shook" so violently that he spilled most of the tea and he could not bring his cup to his mouth. Even when his wife held the cup he could not drink normally, but, as his wife described it, "he slopped the tea into his mouth and gulped it down." When he got up that evening to go to his ship his right arm was twitching and swinging about widely, and "he was throwing his right leg about," but, with some assistance from his wife, he managed to walk. When his wife saw him again, two hours later, the involuntary movements had become much worse, but in the morning he managed to walk home. His condition remained much the same for the next 36 hours, but on the evening of Feb. 10th he became very agitated and unreasonable, turned on his wife as he had never done before, and in such a way that she was afraid of his violence; his involuntary movements were then worse than ever. The next day he remained in the same angry and uncontrollable mood, and in the evening made his way down to the ship. On the fourth morning after the onset of his illness he fell in his house, and that day he was brought to hospital.

Condition on Admission.

When I first saw him, and until his death 15 days later, his condition was as follows. While he was awake his right arm and leg were unceasingly tossed about in a violent chorea. The movements occurred at all the joints of these limbs, but an unusually severe involvement of the shoulder and hip and elbow and knee gave them an amplitude not often seen in chorea. In form they presented every combination of flexion, extension, and rotation; they were quite irregular. They were free, quick movements, unhampered by any degree of spasticity. Their violence was such that the skin had been knocked off the knuckles and other parts of the affected hand, and also of the inner sides of both knees. The movements were continuous during the waking state, though they varied somewhat in intensity, being less when the patient was alone, and worse when he was called up to answer questions or perform test movements. With a great effort the patient could hold the right arm steady for about 20 seconds, every muscle of the limb being then taut in contraction. The right side of the head and face and the tongue were involved in the chorea, and to some degree the right side of the trunk. The patient usually lay with his head and eyes turned to the right, and he seemed to try to put the right hand under his head in order with his head to fasten it down on the bed and so restrain its movements. The movements of the face were less than was to be expected from the severity of the chorea in the limbs. In the early days of the illness articulation, though affected, was still distinct, but later it became greatly slurred. Swallowing was performed by spasmodic gulps. Breathing was always irregular, and was sometimes difficult owing to the irregular movements of the muscles of the throat, chest, and abdomen. All these abnormal movements ceased entirely during sleep. The patient's facial expression suggested great anxiety and restrained anger, and this seemed to be a true reflection of his mental state; during his stay in hospital he was at times irrational and uncontrollable, especially towards night; in the latter part he was at times disorientated, and often in a frenzy. Associated with the movements was a moderate degree of sweating, almost confined to the affected side; the patient while awake always looked hot, and the jactitated limbs felt warm and moist. The body temperature, as registered on the chart, remained steadily at 97° F. until a few hours before death. The temperatures of the two sides of the body were unfortunately not compared.

Neurological Examination.

Further neurological examination revealed few other abnormalities. Voluntary power was normal in all the limbs. There was no sensory loss to pin-prick or light touch; at the first examination, but not subsequently, there seemed to be a slight hyperæsthesia of the choreic arm. The sense of position was normal, and pointing tests, including the Bránáy tests, were accurately performed; pointing with the right hand was accompanied by choreic deviations of the moving limb, and the point indicated was touched by a finger, as it were, in flight. The appreciation of vibration was normal. The tendon-jerks were present in both arms and about equal on the two sides, those in the right arm being, if anything, less; the knee-jerk was definitely less on the affected (right) side than on the left; the ankle-jerks were approximately equal. The plantar responses were both definitely flexor throughout the illness. The abdominal reflexes were not obtained. The optic discs were normal, the pupils were approximately equal, but neither was quite regular; both reacted to light, and as far as could be determined they reacted also to accommodation; the external ocular movements were full, but the eyes when at rest were usually deviated to the right. Except for the abnormal movements in the face, throat, and tongue, the functions of the remaining cranial nerves were normal.

The patient died on the twentieth day from the onset of the chorea. A post-mortem examination was performed by Dr. J. G. Greenfield 12 hours after death, and the brain was hardened for a week in 10 per cent. formol saline before being cut. Subsequent section showed a recent hæmorrhage destroying the body of Luys of the left side—i.e., of the opposite side of the body to the chorea; except for scattered hæmorrhagic points there was no other lesion in the brain.

The examination of serial microscopic sections showed that in its vertical extent and antero-posteriorly the injury corresponded closely with the limits of Luys's body, and in lateral extent it transgressed these limits only by one or two millimetres in each direction. A small dorsal fragment of the corpus Luysii remained. The red nucleus was not reached by the hæmorrhage at any level, and none of the known important fibre-tracts was interrupted.

The photograph which is shown here (Fig. 2) is that of a horizontal section of the brain, which passes on the left side through the lesion below its middle, and through the upper half of the red nucleus; the right half of the brain is cut appreciably lower (as is shown by the section of the optic tract), and only a small portion of the body of Luys of that side is seen. The actual area of destruction is seen surrounded by a zone of staining. Its length at this level was almost exactly 1 cm., and its breadth ½ cm., but at a higher level its breadth was slightly greater. A more detailed description of the pathological anatomy is given in the original paper.[1]

FIG. 1.

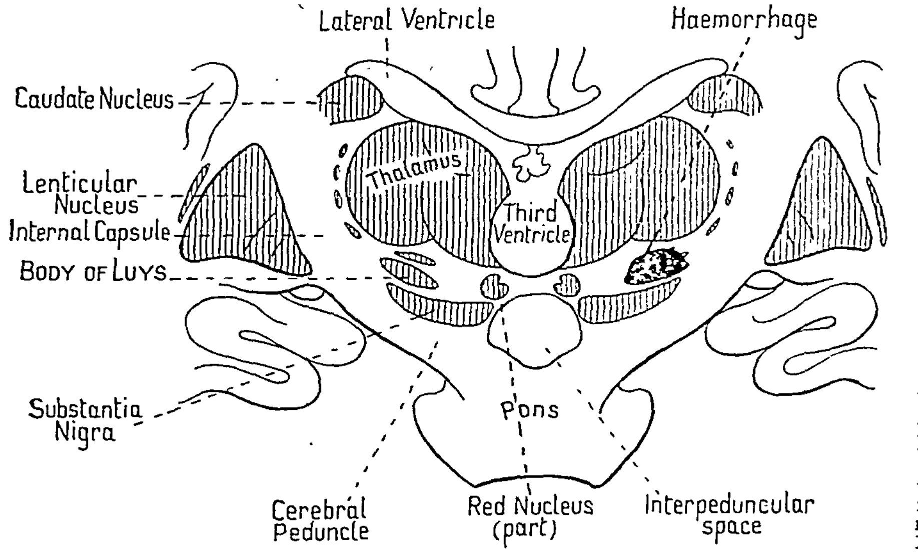

Diagram of a vertical transverse section of the brain to show the anatomical relations of the body of Luys and the extent of the hæmorrhage in the case described.

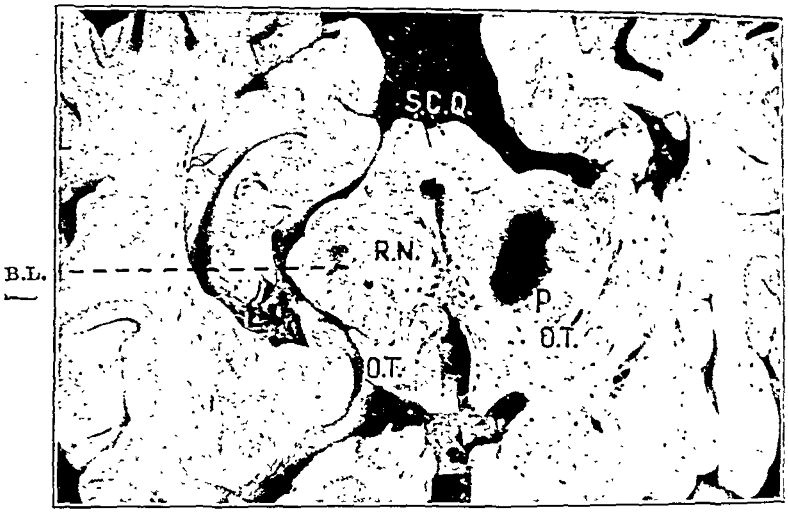
Similar Cases in the Literature.

It is impossible to assess the physiological significance of the findings in such a case except in conjunction with similar findings and with experimental work. There are in the literature of the last 50 years 12 cases, sufficiently described, in which *localised lesions of the body of Luys* have been found after death, and a number of other cases in which the body of Luys was involved in more extensive lesions. Closely comparable to the case described above are those of Fischer, Campora, Pette, Canfield and Putnam, Economo and Jakob, of which I give the following brief notes:—

FIG. 2.



Horizontal section of the brain passing through the lower half of the hæmorrhage. The area of actual destruction is surrounded by a zone of staining. B.L. = body of Luys; R.N. = red nucleus; S.C.Q. = superior corpora quadrigemina; P. = cerebral peduncle; O.T. = optic tract; and L.V. = left ventricle.

Fischer, 1911.—Female, aged 72. Sudden onset of left hemichorea with very large movements; face considerably affected. Articulation and swallowing disturbed. No mental disturbance. Death on the fourth day.

At post-mortem examination a hæmorrhage was found destroying the right body of Luys "and only this." There was a superficial cortical defect on the orbital surfaces of both frontal lobes.

Campora, 1922.—Female, aged 70. Abrupt onset of violent chorea in the left side. Face involved; articulation and swallowing affected. Pronounced hypotonia of affected side. Some psychic disturbance. Death after five weeks.

At post-mortem examination a small hæmorrhagic fissure was found in the *right* subthalamic region, 1 cm. in length, running transversely above the pes pedunculi. It destroyed most of the corpus Luysii, leaving only its most lateral part intact; medially, it extended into Forel's field and just touched the capsule of the red nucleus; the internal capsule was not involved.

Pette, 1922.—Female, aged 69. *Carcinoma* of the breast three years before. Sudden onset of chorea of the whole of the left side. Death four weeks later.

Post-mortem examination showed a carcinomatous deposit the size of a pea in the right regio-*subthalamica*; the body of Luys was mostly destroyed (private communication); red nucleus, thalamus, corpus striatum, and cerebellar peduncles all intact.

Canfield and Putnam, 1884.—Male, aged 59. Slight right hemichorea for several weeks, then sudden exacerbation. Face little involved. Articulation affected. No sensory loss. Knee-jerk and ankle-jerk normal on right, absent on left. The patient could walk without assistance. Death three weeks after the onset of severe chorea.

Post-mortem examination showed a hæmorrhagic softening the size of a large pea "in the medial half of the left crus, opposite the posterior portion of the thalamus; it involved the substantia nigra and the pes beneath to a depth of 5 to 6 mm., and the tegmentum above almost to the nucleus ruber. The only ganglionic matter involved besides the substantia nigra was the so-called ganglion of Luys."

v. Economo, 1910.—Male, aged 71. Sudden onset of violent chorea of the left side 24 hours after a slight stroke causing some weakness of this side. Articulation affected. Transient right hemi-amblyopia. Mental disturbance. Death seven days after the onset of the chorea.

Post-mortem examination revealed a hæmorrhage the size of a cherry-stone lateral to the red nucleus, in the substantia nigra and in the tegmentum, involving the regio subthalamica and the corpus Luysii, and extending ventrally into the pes.

Jakob, 1923.—Female, aged 75. Sudden onset of left hemichorea with large movements. Conjugate deviation of the eyes sometimes to right, sometimes to the left. Condition remained unchanged for three weeks; then 24 hours before death the patient became comatose and the limbs of the left side were at rest and very flaccid. On the right side some spasticity. Death from broncho-pneumonia on Nov. 3rd, 1921.

At post-mortem examination a recent hæmorrhage was seen, entirely destroying the body of Luys on the right side, and strictly confined to this ganglion, pushing Forel's bundles H 1 and H 2 upwards: it was sharply demarcated from the internal capsule and the substantia nigra. Medially, it extended beyond the bounds of Luys's body, but did not touch the red nucleus. Many hæmorrhagic points in the basal ganglia of both sides. Some small hæmorrhagic foci in the left internal capsule.

With these I think we may group the following case, though its anatomical description is not quite precise.

Magnan,[2] 1870.—Male, aged 73. Sudden onset of right hemichorea. Violent movements. Death after five days.

Post mortem "a section made through the left cerebral peduncle at its insertion into the optic thalamus revealed a hæmorrhagic focus of the size of a small nut." This was the only recent cerebral lesion.

Confirmatory evidence of the results of injury to the corpus Luysii is afforded by the remaining cases, in which there was more than one small lesion in the brain, one of the foci in each case destroying Luys's body.

Such cases have been recorded by Greiff, Touche, Bianchi (second case), Bremme and Matzdorff.[3] In all of these the clinical syndrome was the same as in the cases already described, with some complication corresponding to the other lesions. In Bremme's case the damage was caused by secondary carcinomata, in Bianchi's by patches of sclerosis, and in the other cases by hæmorrhage or thrombosis. Matzdorff's report requires special mention; it was apparently in the press at the time at which the paper I have referred to was read, and the author, citing seven of the cases I have mentioned, described independently as "The syndrome of the corpus Luysii" the main elements of the symptom-complex put forward under a similar title in my paper. But Matzdorff relates that his patient had been seen during life by Prof. Jakob, and the latter, who had had a similar case several years before, expressed the opinion (Wahrscheinlichkeitsdiagnose) that there was a lesion of the corpus Luysii of the opposite side of the body to the chorea. This must surely be the first case in which such a diagnosis has been correctly made, even tentatively, during life, and it marks a stage in the knowledge of the subject. Pathologically Matzdorff's case is important because the softening was entirely confined within the limits of Luys's body.

Of less physiological value than the foregoing, but still worthy of mention, are cases in which the corpus Luysii was involved in a lesion which extended widely beyond its borders. Such are Bianchi's first case (tuberculoma), and the cases of hæmorrhage recorded by Lewandowsky and Stadelman, and by Lloyd and Winkelman; probably the case recently described by Weil[4] falls also into this group. In all of these cases the same choreic syndrome was present during life.

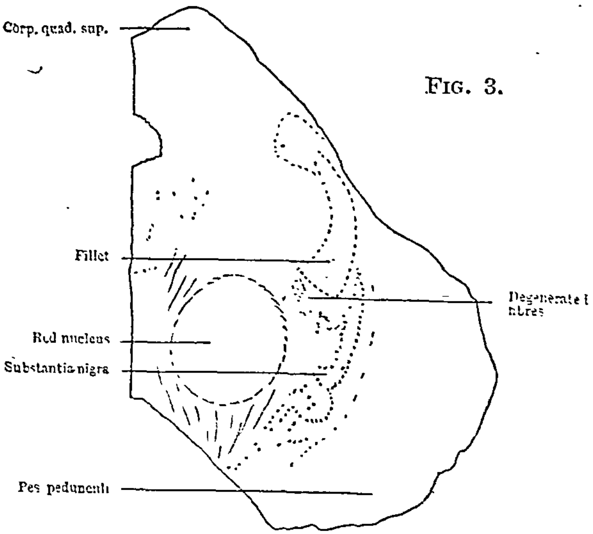
To the experimenter the body of Luys is not easily accessible, and the only experiments actually involving it are those of d'Abundo.[5] He found that in kittens his lesions of the subthalamic region (including Luys's body) invariably produced a chorea of the opposite side of the body, and rotation of the head to the side of the chorea.

Fibres Descending from the Corpus Luysii.

It has been said that the efferent connexions of the corpus Luysii are very imperfectly known. In my case, blocks of cerebral tissue from above and below the site of injury were impregnated by the Marchi method, and these when cut showed a small but definite bundle of degenerated fibres beginning immediately caudal to the destroyed corpus and passing down the mid-brain (see Fig. 3). It lay immediately behind the substantia nigra, and soon joined the medial margin of the medial fillet. It seems most probable that the fibres composing this bundle issue actually from the corpus Luysii, and it is consequently to be expected that a small lesion interrupting them would give rise to the same symptoms as an injury to the body of Luys itself. However that may be, there are in the literature of the last 50 years only two cases in which hemichorea was attributable to a focal lesion at a lower level than the corpus Luysii, and in both these cases the sites of damage, though widely divergent, were so situated that this bundle of fibres was interrupted. The first is a case by Bianchi in which the only damage in the left half of the brain (to account for a right hemichorea) was a patch of sclerosis which lay mainly in the middle third of the pes pedunculi and had spread backwards through the substantia nigra to involve the medial portion of the fillet. The second is a well-known case described by Bonhoeffer in which the main lesion was due to a carcinomatous mass at the decussation of the superior cerebellar peduncles, but to the left of this there was a small deposit interrupting the medial margin of the left fillet; the patient had had a right hemichorea. With the knowledge of the other cases now at our disposal it seems legitimate to ascribe the symptoms in this case to the latter lesion.

In animal experiments chorea of the opposite side of the body has been produced by Economo and Karplus[6] by lesions which interrupted, inter alia, the medial margin of the fillet, and by Lafora[7] by lesions directed towards the superior cerebellar peduncle, and therefore also interrupting these fibres. Chorea, as far as I have discovered, has not been obtained experimentally by any lesions other than those mentioned.

FIG. 3.



Outline drawing of a section through the upper part of the left half of the mid-brain to show the position of the degenerated fibres.

It is therefore in conformity with the clinical and experimental facts that interruption of the fibres which appear to descend from Luys's body gives rise to symptoms similar to those resulting from injury to the body itself. Unfortunately it has not been possible to follow the degenerated fibres to their termination, and their ending is unknown.

The Syndrome of Destruction of the Corpus Luysii or of its Descending Fibres.

A study of the foregoing cases in more detail than it is possible to give them here enables us provisionally to attribute a group of symptoms to the destruction of the corpus Luysii or interruption of its descending fibres, with the consequent release or disturbance of the function of other structures. The chief symptom is a violent chorea of the opposite side of the body, with unusual involvement of the shoulder and hip, and, therefore, with movements of unusual amplitude. The affection of the face, according to nearly all the descriptions, is less than one would expect from the amount of choreic movement in the limbs. Speech, swallowing, and respiration are all involved in the chorea. The movements cease entirely during sleep. The tendon-jerks of the affected side are usually less than those of the other, indicating a moderate degree of hypotonia.

In a number of cases it is recorded that the temperature of the choreic side was higher than that of the other half of the body, and in my case there was some unilateral sweating.

In nearly every case there has been a mental disturbance—at first chiefly an emotional change (excessive anxiety), and afterwards loss of memory, confusion, and disorientation.

There are no signs of pyramidal disease, no loss of superficial sensation or of sense of position, no defects in the pointing tests.

In all the recorded cases in which the syndrome was fully developed death has resulted in a few weeks, the maximum duration of life recorded after a sudden onset of violent chorea being eight weeks (Greiff). But with less severe symptoms the period of survival may be very much longer. In all the cases in which the mode of death can be ascertained, except Bonhoeffer's case in which death was due to erysipelas, the patients died of broncho-pneumonia. Touche's patient, who lived for a year after the onset of the chorea, had three attacks of broncho-pneumonia during that time. It is remarkable that none of the patients died of cerebral hæmorrhage or of cardiac failure. I think that the tendency to broncho-pneumonia is possibly to be correlated with the respiratory disturbances of the chorea and to be included as part of the fully expressed syndrome.

Remarks on the Pathogenesis of Chorea.

Since chorea commonly occurs in association with widespread inflammatory or degenerative changes in the brain, it has perhaps not been generally realised that it might result from a focal lesion. In this paper no reference is made to the inflammatory or degenerative choreas, but we must ask ourselves in what way focal lesions in the situations we have described can result in chorea. It is now generally conceded that chorea is a "release phenomenon," i.e. that it arises from the excessive or irregular activity of intact structures from which a controlling or guiding influence has been withdrawn. The cases that have been related do not indicate in what structures the impulses arise which originate the choreic movements, nor what structures must be intact in order that chorea may occur. Two factors indicate, however, that the impulses arise at a lower level than the body of Luys and that the controlling influence over them is normally exerted by the body of Luys itself. In the first place, we are dealing with a descending anatomical system of fibres; fibres arise in the lenticular nucleus and pass to the body of Luys, and another set of fibres arising in the body of Luys continues the path downwards to the mid-brain. Such a system must, by reason of its anatomical arrangement, exert its action downwards; in other words, the control which the destruction of Luys's body apparently interrupts is a downward-directed control, and so the impulses over which it is normally exerted must be arising at a lower level. Secondly, there is no valid evidence that focal injuries above the body of Luys result in chorea. Numerous animal experiments have been performed, of which those of Kinnier Wilson[8] on the lenticular nucleus and the recent series by Delmas-Marsalet[9] on the caudate may be mentioned, and in no instance has chorea or any symptom comparable to chorea resulted from a lesion of these structures. Of clinical cases of pure chorea resulting from focal lesions nearly all the recorded instances have already been mentioned. It is true that there remain four—those of Vogt,[10] Conos,[11] Austregesilo and Gallotti,[12] and Fragnito and Scarpini[13]—and that in all of these the chorea has been attributed to a lesion in the caudate or putamen. But it can be said without fear of contradiction that as a basis of argument the first three of these are valueless. The fourth is a much more important record, but is open to certain objections, and the authors, who express themselves with great reserve on its merits, state definitely that they are unwilling to give any general application to their findings. Consequently we must for the present be guided by the experimental evidence and assume that focal lesions of the caudate or lenticular nucleus do not give rise to chorea. If chorea does not occur unless the lesion is as low in the system as the corpus Luysii, and does occur when that structure is damaged, the control which normally prevents chorea must be exerted by the corpus Luysii itself. As long as that primary control is intact, chorea from a focal lesion does not seem to occur.

Physiological Action of the Corpus Luysii.

Of the physiological action of the corpus Luysii little can yet be said, except that it exerts a control over impulses arising in certain lower structures which are probably situated in the mid-brain. There is no unanimity as to the nature of the impulses which cause chorea, and until we know their nature we cannot deduce the normal function of the corpus Luysii from the *symptoms* liberated by its destruction. The anatomical connexions of the corpus Luysii with the lenticular nucleus suggest that there is a higher control of its activities represented in certain cells widespread in the striatum and pallidum, and it may be that by these nuclei the function of Luys's body is normally directed in relation with other cerebral functions.

A NOTTINGHAMSHIRE ORTHOPÆDIC HOSPITAL.—The Duke of Portland has given a large site at Harlow Wood, near Mansfield, for the erection of an orthopædic hospital. Owing to legal difficulties a public Guarantee Company has been formed for its erection. Last year, in Nottingham alone, there were more than 100 cripples for whom treatment was not available.

A CLINICAL STUDY OF THE HUMAN AND BOVINE TYPES OF TUBERCULOSIS IN MAN.

By JOHN T. MORRISON, M.B. Edin., F.R.C.S. Eng.,
HON. SURGEON, ROYAL SOUTHERN HOSPITAL, AND CONSULTING SURGEON, CITY SANATORIA FOR TUBERCULOSIS, LIVERPOOL.

The investigations out of which this paper developed were originally undertaken by Prof. J. M. Beattie, of the University of Liverpool, to determine whether the incidence of human and bovine tuberculosis was the same in Liverpool as in other parts of the country. The bacteriological work has all been carried out by him from clinical material supplied from the City Sanatoria, the Royal Liverpool Children's Hospital, the Liverpool Stanley Hospital, and private practice. It is therefore fairly representative of all types of non-pulmonary tuberculosis and of various ages and social strata. The correlation of the clinical conditions with the bacteriological findings brought out many points of interest which are important in so far as they contribute to a more accurate knowledge of the disease. My conclusions should be regarded as indications rather than demonstrations of the truth. So far as they go, I think they are justified by ascertained facts, but larger numbers are needed before generalisations can be made. Of necessity a certain amount of selection has crept in. The material is from consecutive cases, but since, as a rule, it is the more hopeful cases that reach the operating-theatre the mortality results are of no absolute value. On the other hand, a certain amount of comparison between different groups is permissible.

One hundred cases were investigated bacteriologically during the years 1923–24–25. One or two have been excluded as certainly not tuberculous. Some patients cannot be traced, and so final conclusions cannot be drawn about them, although previous notes render them useful for certain statistics.

Inoculation Failures.

A considerable number of cases inoculated, although clinically undoubted cases of tuberculosis, gave no result in the test animals. Of these "negative" results one should be eliminated, as the patient had a severe streptococcal infection and the animals died of streptococcal septicæmia. This leaves 31 cases, almost one-third, for inquiry. The material used in these 31 cases was: in 66 per cent. the caseous debris of softening glands or actual pus; in 25 per cent. caseating bone foci; and peritoneal fluid and tuberculous granulation tissue in 4 per cent. each. As the proportions are practically identical in the series of cases proved definitely bovine, it seems that the source of the material and its physical properties have no important bearing on its failure to produce disease in animals. In other words, although pus was used in a considerable percentage of cases—and tuberculous pus is notoriously deficient in tubercle bacilli—the negative results cannot be attributed to this factor, as pus was used in just as many cases which gave positive results. So far as it goes, this is an argument against the criticism that paucity of organisms in the material used was responsible for the absence of tuberculosis in the laboratory animals.

It may be said that such organisms as were present were enfeebled by exposure to powerfully antagonistic bodies in the serum of patients highly immunised against tuberculosis. If this be so, the high state of immunity is not reflected in the clinical progress of the patients. In those under consideration the recovery-rate (or proportion of apparent cures) was only 73 per cent. None of the 18 cases of undoubted bovine tuberculosis traced for two years or over showed any signs of active disease—i.e., the recovery-rate was 100 per cent. I do not think that the effects of general immunity in the patient are of any great importance here. On the other hand, local conditions seem to have a bearing upon the results. It is conceivable that fibrosis, for instance, is inimical to the organisms in lesions in one part of the body, while in other parts the disease might even be progressive. The average duration of the lesion in the cases giving "no result" was 4·3 years (though several cases had apparently relatively short histories), while the "human" cases had lasted 2·3 years and the "bovines" only just over one year. That the results were not merely fortuitous is shown by the fact that repetition of the inoculations confirmed the original negative finding in several instances.

In case it should be pleaded that these patients were not tuberculous at all, those in whom any clinical doubt arose have been excluded. The proportion of cases of actinomycosis and syphilis which simulate tuberculosis is very small. No case giving a positive Wassermann reaction has been included. The table shows that, in the distribution of the disease over the different organs and systems, the "no result" cases represent almost exactly the average between those of definitely human and bovine origin. The negative cases, therefore, are probably derived fairly equally from both types of infections, so that it cannot be said that one type of bacillus is more frequently at fault, or is more easily influenced by the local curative actions of the body, than the other. For this reason the "no result" cases have been ignored in the statistical inquiries into the human and bovine cases.

—	Bovine.	Human.	No result.
Lymph glands	25	11	20
Bones and joints	5	13	7
Abdomen	2	0	2
Genito-urinary	1	1	0
Miscellaneous	1	1	1

Regional Distribution.

The bovine bacillus is found to account for 75 per cent. of the cases of tuberculous glands in the neck. That is rather less than has been found in certain other districts, where the percentage has been placed as high as 90 per cent.[1] Inquiry into the age incidence may account for this apparent variation. Bovine infections were present in only about 28 per cent. of the bone cases. The figures relating to abdominal and genito-urinary cases—mainly because they are relatively seldom submitted to operation—are so small as to be valueless. In the main the figures are comparable to those for the country generally.

A study of the age factor throughout the whole series shows that 65 per cent. of the human infections were over 12 at the age of apparent onset, while 35 per cent. were 20 or over when symptoms first appeared. Among the bovine cases, on the other hand, only 15 per cent. were over 12 when attention was drawn to the disease. Of these 15 per cent., although the infection was bovine, three out of the five were not only over 12 but actually between 20 and 25 when evidence of tuberculosis was first obtained. While, roughly, 75 per cent. of all bone tuberculosis is due to the human bacillus, in patients over 15 the figure rises to 82 per cent., and in those under 15 about 70 per cent. is human in origin. This figure is one of great significance.

Of the cases of lymphatic gland infection in children 16 per cent. yielded the human type of organism and 84 per cent. the bovine. This more closely approximates to the 90 per cent. quoted above from the published results of work done entirely amongst children. Nevertheless, the fact remains that in Liverpool 16 per cent. of cases of glandular tuberculosis are due to human bacilli—i.e., infection from active cases of phthisis. In contrast to this 62 per cent.

---

[1] A. P. Mitchell: Infection of Children with Bovine Tubercle Bacillus, Brit. Med. Jour., 1914, i., 125.

of glandular disease in adults is due to the human tubercle bacillus. In fact, in adults about 72 per cent. of all surgical tuberculosis is the result of infection with the human organism. That implies that a very large proportion of cases of adult non-pulmonary tuberculosis have also a pulmonary focus —active or latent. This should increase the gravity of the prognosis in these cases, should make prolonged after-care imperative, and should be a warning against the indiscriminate use of general anæsthetics, which may aggravate pulmonary disease. An X ray of the chest should always be taken before operation on any adult with surgical tuberculosis.

Family History.

It was thought that a study of the family history would in many instances give a clue to the type of disease present—i.e., that a history of phthisis in a member of the older generation would be found in infections with the human bacillus, and that in bovine infections the older generation would be healthy, and other members of the same generation diseased. Here, however, great difficulties are encountered. There is a very widespread feeling that it is disgraceful to have a case of tuberculosis in the family. Unfortunately, the sense of disgrace does not lead to the general adoption of a more hygienic way of life, the use of non-tuberculous milk, and stricter measures to prevent the spread of infection, but only to concealing the shameful fact or to heaping up mounds of sand in which to bury the head, so that at least the horrid thing is out of sight. Infection of collateral members of the family is surprisingly seldom reported in bovine infections, though, of course, striking instances do occur. This is another indication that the soil is at least as important as the seed in the development of tuberculosis. In human cases, on the contrary, a bad or decidedly suspicious history of pulmonary disease was found in 31 per cent. Over and over again one can elicit nothing more than "grandmother always had a cough and mother died of pneumonia."

Apart from a study of the family history, attempts at determining the portal of entry were singularly unsuccessful. It was definitely recorded that, among the bovine cases, two apparently originated in glands draining the area in which an open wound had existed a short time before. In bovine cases the milk naturally falls under special suspicion. In four cases, one of which was in a well-to-do intelligent family, it was stated that the milk had always been boiled. This, of course, proves nothing, for such matters are often left to maids, who may be untrustworthy. Moreover, other articles of diet, such as butter and cream, may be carriers of the bacillus. The tonsils were diseased and the teeth carious in many patients with cervical glandular disease, but in several others they were not obviously at fault. Little weight, unfortunately, can be attached to this observation as, apart from the possibility of tuberculous infection passing through a tonsil without leaving indisputable evidence behind, it has been definitely shown that naked-eye examination is no criterion as to the presence or absence of actual tuberculous disease in a tonsil.[1]

Results of Treatment.

The results of treatment are strikingly different in the different groups. For instance, as already stated, all the 18 bovine cases traced were found in good health, and their lesions quiescent, while no less than 18·75 per cent. of the human cases were dead within three years; 68·75 per cent. were cured or apparently cured. I do not think this necessarily means that the bovine infections are harmless, while the human are deadly. Apart from the long period of illness, the expense of treatment, and the permanent crippling often caused by bovine infections, many patients die in the early years of life from meningeal, pulmonary, and abdominal tuberculosis, and are never seen by the surgeon.[2] The course of the two infections is apparently very different. Those due to the bovine organism begin, as a rule, early in life, though not necessarily in the very earliest years, and may lead to a comparatively acute and virulent process. Should this not prove fatal, the manifestations of the disease become more and more chronic until after early adult life it practically disappears. Many believe that the human infection is contracted early—i.e., within the first four years of life—and that thereafter, if not rapidly fatal, it lies latent, perhaps for many years. Be that as it may, in "surgical cases" the disease is one that tends to attack those of maturer years (65 per cent. over 12 at the time of apparent onset) and, unlike the bovine type, it never disappears, and all ages are liable to suffer. It may become very chronic, but the immunity established evidently falls far short of that produced by the bovine organism, as is shown by the very considerable mortality in the human variety.

---

[2] Dr. Louis Cobbett's evidence, Report of Royal Commission on Tuberculosis, 1907.

SOURCES OF INFECTION IN NON-PULMONARY TUBERCULOSIS.

By C. O. STALLYBRASS, M.D. Lond.,
D.P.H. Liverp.,
ASSISTANT MEDICAL OFFICER OF HEALTH FOR THE CITY OF LIVERPOOL.

For the past seven years I have noted, from the reports of our sanitary inspectors on cases of non-pulmonary tuberculosis, whether there was a history of exposure of the patient to a pulmonary case occurring in the patient's family. In all these patients there is a considerable presumption that the infection was of human origin. The total number of cases so examined is now 4469, and these are presented in Table I., separated according to the anatomical site, on the usual classification. The numbers are sufficiently large to have some statistical validity.

TABLE I.

City of Liverpool.—Cases of non-pulmonary tuberculosis in 1921–27, divided into Group A—*those with no history of exposure, and Group B—those with a history of exposure to open cases of tuberculosis occurring within the family of the patient.*

Site of disease.	A.—No exposure.	B.—Exposure.	Proportion of total expressed per cent.		Difference of percentage.*	Probable error of difference (per cent.).
			A.	B.		
Bones and joints ..	974	89	24·3	19·3	−5·0	±0·41
Abdominal	859	116	21·4	25·1	+3·7	±0·45
Peripheral glands ..	1277	156	31·9	33·8	+1·9	±0·49
Meninges and brain	418	61	10·4	13·2	+2·8	±0·39
Skin..	124	15	3·1	3·2	+0·1	±0·80
Urinogenital ..	92	3	2·3	0·7	−1·6	±0·97
Other, or ill-defined	264	21	6·5	4·6	−1·9	±0·32
Total	4008	461	99·9	99·9	—	—

* This column gives the excess (or defect) of the percentage of cases occurring in Group B over the percentage of cases occurring in Group A.

The significance of these figures lies in the last two columns, which give (1) the excess or deficiency of the percentage of cases having a history of exposure to infection in comparison with the percentage of cases having no such history, and (2) the probable error of this difference in percentage. The usual criterion of the significance of a difference of two rates is that it should be three or more times its probable error. With this proviso the following deductions may be made from the table. In Liverpool—

1. Tuberculosis of the bones and joints is significantly more frequent in those having no history of exposure to a human source of infection.
2. Tuberculosis of meninges and abdominal tuberculosis are significantly more frequent in those having a history of exposure.

3. Tuberculosis of peripheral glands is significantly in excess in those known to be exposed to human infection, but the significance is not so high as in 1 and 2.

4. The other groups either lack precision or are not numerous enough to be significant.

The deductions from these figures indicate that tuberculosis of bones and joints is more often of bovine origin than meningeal, abdominal, or, with less certainty, peripheral glandular tuberculosis. This inference is somewhat contrary to the usual opinions which are based largely on the work of Eastwood and Griffith, and of Park and Krumwiede. Griffith has given figures of cases bacteriologically investigated; they indicate that 46·5 per cent. of cervical glandular cases, 41·3 per cent. of abdominal cases, and 18·3 per cent. of bone and joint cases occurring in children were caused by bovine bacilli.

I give now a table (II.) of non-pulmonary cases of tuberculosis, slightly modified from figures given by Dr. A. S. Griffith at the National Milk Conference in London in 1922. I have computed the probable errors of the percentage.

TABLE II.*

—	Cases.	Bovine and per cent.	Probable error.
Cervical glands	116	54 (46·5)	±3·12
Bone and joint	476	87 (18·3)	±1·20
Lupus	126	64 (50·8)	±3·00
Genito-urinary	17	3 (17·6)	±6·23
Post-mortem material ..	159	39 (24·5)	±2·30
Meningitis	12	2 (16·6)	±7·25
Total	906	249 (25·8)	±0·95

* These figures, unfortunately, do not give the abdominal cases.

Owing to their numerical insufficiency the figures of bacteriological examination of material from cases of non-pulmonary tuberculosis are not beyond statistical criticism, despite the immense labour involved in obtaining them. Mr. E. D. Rudolf[1] performed this task some years ago, and his results are given in Table III.

TABLE III.

Age-period in years.	Total cases.	Bovine infections and per cent.	Maximum variation possible.
0–5	47	14 (29·79)	18·87
5–10	108	31 (28·71)	12·31
10–16	62	7 (11·29)	11·37
16–25	15	3 (20·0)	29·2
Over 25	29	0 (0·0)	0·0
Total	261	55	—

It appears from these figures that the number of cases occurring in persons over 16 years of age is insufficient for comparison, and the figures in this respect are not a fair sample of the population. In order, then, to make a useful comparison it is necessary to confine attention to children. The figures given in Table IV., from information provided by Dr. B. T. J. Glover, show the distribution into adults (over 15 years) and children, of 2625 cases on the records of the tuberculosis dispensaries in 1927, and are probably a fair sample of the whole.

TABLE IV.

Cases of non-pulmonary tuberculosis among persons on records of tuberculosis dispensaries in Liverpool, 1921–27.

Classification.	Adults and per cent.	Children and per cent.	Total.	Children. Per cent. of total at site.
Bones and joints	277 (36·40)	469 (25·16)	746	72·6
Abdominal ..	83 (10·91)	471 (25·27)	554	85·0
Peripheral glands	314 (41·26)	764 (40·99)	1078	70·9
Other	87 (11·43)	160 (8·58)	247	64·8
Total	761 (100·00)	1864 (100·00)	2625	71·1

The incidence upon adults and children is not markedly different except in the case of abdominal tuberculosis, which is predominantly a disease of children, and to a lesser degree in respect of bone and joint tuberculosis which has a somewhat disproportionate incidence upon adults. I therefore returned to my records and abstracted the cases with a history of exposure, dividing them into adults and children. The result is shown in Table V.

TABLE V.

Cases with a history of contact with a pulmonary case.

Classification.	Adults and per cent.	Children and per cent.	Total.	Ratio of children to adults (per cent.).
Bones and joints	24 (22·64)	65 (18·31)	89	2·7
Abdominal ..	10 (9·48)	106 (29·86)	116	10·6
Peripheral glands	51 (48·11)	105 (29·58)	156	2·0
Other	21 (19·81)	79 (22·25)	97	2·8
Total	106 (99·99)	355 (100·00)	458	3·31

It would take too long to find the proportion of children in all the cases of non-pulmonary tuberculosis, and so I take the records of the tuberculosis institutes, in which the children amount to 2625 out of 4469, or more than half the total, and, with this proportion as a basis, eliminate from the total given in Table I. the proportion which may be regarded as probably adults (Table VI.).

TABLE VI.

Estimated cases of non-pulmonary tuberculosis *in children* in the City of Liverpool during 1921–27, divided into (A) those with *no* history of exposure, and (B) those with a history of exposure to a pulmonary case of tuberculosis.

Site of disease.	A.—No exposure.	B.—Exposure.	Proportion of total expressed per cent. A.	Proportion of total expressed per cent. B.	Difference of percentage.*	Probable error of difference (per cent.).
Bones and joints ..	772	65	24·18 ±1·01	18·31 ±1·38	−5·87	±1·71
Abdominal	829	106	25·97 ±1·05	29·86 ±1·64	+3·89	±1·95
Peripheral glands ..	945	105	29·60 ±1·09	29·58 ±1·63	−0·02	±1·96
Other, or ill-defined	646	79	20·24 ±0·96	22·25 ±1·49	+1·01	±1·77
Total	3192	355	99·99	100·00	—	—

The deductions from Table I. have to be somewhat modified for children:—

1. Bone and joint tuberculosis is significantly in excess in those having *no* history of exposure to human infection.

2. Abdominal tuberculosis is in slight excess in those having a history of exposure.

3. Peripheral glandular tuberculosis occurs with as high a frequency among those exposed as among those not known to be exposed to human infection.

There is therefore a direct contradiction between the figures I now publish and the results of bacteriological investigation. Possibly the discrepancy arises from differences in the age-distributions of the populations investigated; or there may be geographical differences; or the cases bacteriologically investigated may be representative of only a portion of the whole—e.g., the more severe cases.

It is of some interest to note that, although the collection of the data has occupied seven years, their analysis has taken only two days; yet it is this comparatively slight labour which is usually shirked. Use has been made of Pearson's tables for the value of χ, Miner's tables of $\sqrt{pq}$, Barlow's tables of squares, and a calculating machine for the multiplication and division.

---

[1] THE LANCET, 1922, i., 1146.

I have to express my thanks to Dr. A. A. Mussen, Medical Officer of Health for the City of Liverpool, for permission to publish these figures.

THE PERMANENCE OF THE SCHICK NEGATIVE STATE.

By H. J. PARISH, M.D., M.R.C.P. EDIN.,

AND

C. C. OKELL, *M.C.*, M.B., M.R.C.P. LOND.

(From the Wellcome Physiological Research Laboratories, Beckenham.)

It is customary to assume that the state of immunity to diphtheria which is indicated by a negative Schick test is permanent. This is suggested by much experimental work on the duration of active immunity, but, because modern methods of diphtheria prevention are of such recent date, it is impossible to examine the expectation by actual experience in human beings. This paper records the results of retesting children at intervals after a negative Schick test was obtained, the maximum interval being seven years. An investigation has also been made of the capacity of response to artificial immunisation of any who may have become positive after having once been negative. 973 children were retested one to seven years after the first negative Schick test. All were negative with the exception of 28 (2·9 per cent.). 541 children were retested after one to three years, 191 after three to five years, and 241 after five to seven years. After one to three years the percentage of positives was 2·6, after three to five years 5·3, and after five to seven years 1·7, differences which are probably not significant.

The 973 children may be subdivided into two groups—viz., 533, who were negative to the original Schick test one to seven years previously, and 440, who were positive on the original Schick test and became negative only after injections of prophylactic mixtures (vide table). 527 children (98·9 per cent.) of the 533 who were negative on the original Schick test one to seven years previously were read as negative on retest, and 6 (1·1 per cent.) as positive. 418 (95 per cent.) of the 440 in the immunised group were negative on retest and 22 (5 per cent.) were positive. It will be seen that there is little difference in the Schick-positive rate of the two groups. Further tests may, however, confirm the observation that children who have been immunised by artificial methods show a somewhat higher percentage of positives on retest than those who have become immune in response to the weaker stimuli which they may receive naturally. It may be possible that some individuals can be immunised only by the larger stimuli introduced in prophylactic mixtures, and that these people are prone to lose some of the antitoxin they may thus with difficulty acquire. One or two individuals who gave faint reactions may have been wrongly read as positive in our recent retesting, but it is better to read as positive one or two doubtful reactors who are really immune than to pass as Schick-negative a susceptible subject. The Schick level of immunity corresponds to about 1/100th to 1/30th of a unit of antitoxin per c.cm. of blood. The Schick-negative reactor contains more than this amount and the Schick-positive reactor less.

Group 1.—533 Children Negative on Original Test.

In six children who were originally Schick-negative one to seven years previously a positive Schick result was obtained, indicating a quantity of antitoxin less than 1/50th of a unit per c.cm., but four of the six became negative within a brief interval of the Schick test injection. Thus, two weeks after the Schick test was made, a blood sample from one child was examined and found to contain half a unit per c.cm. Blood samples from two other children contained 1/10th unit of antitoxin per c.cm. within one week of the Schick injection, and a fourth child had 1/100th unit in two weeks and gave a Schick-negative reaction in three weeks. Only 2 (0·4 per cent.) of the children (italics in table) required an injection of an immunising mixture. One had no detectable antitoxin in seven days, was given an immunising injection of toxoid-antitoxin at 14 days, had 1/100th unit at 21 days, and was definitely negative a fortnight later. The other gave a positive reaction to a second re-Schick one week after the first, had less than 1/1000th unit of antitoxin, and was given 1·0 c.cm. of an immunising mixture after two weeks and had 1/250th unit of antitoxin in four weeks. This child has recently had another 1·0 c.cm. dose of a prophylactic mixture and is still under observation.

The first four cases afford a parallel to the experiments of Glenny and Allen (1922) on rabbits and guinea-pigs; they found that even 1/20th of a Schick test dose might act as a "secondary stimulus" (Glenny and Sudmersen, 1921), causing a rapid production of antitoxin in an animal which had once been actively immune but which had subsequently lost some or all of its circulating antitoxin. The present investigations have amply confirmed Glenny's observations, and there is no room for doubt that such a small amount of toxin as 1/50th of the guinea-pig minimal lethal dose has a pronounced influence on the amount of circulating antitoxin actively produced, even of such a large animal as a human being. This point has already been discussed by O'Brien (1926), who instanced six cases in which a Schick test dose produced a demonstrable rise in antitoxin in actively immune subjects. Similar observations have been made by Kellogg and Stevens (1927).

Group 2.—440 Children Positive on Original Test and Negative immediately after Immunisation.

Twenty-two children (5 per cent.) in this group were positive on retest one to seven years later, but, as in the first series, all but 2 (0·4 per cent.) developed antitoxin rapidly in response to the stimuli of Schick injections. It will be seen from the table that five of the children were still positive or partially positive on a second re-Schick in the second or third weeks, but one week later all five had 1/25th to 1/5th unit of antitoxin. Two reactors who were more refractory (italics in table) were a brother and sister at a poor-law institution who had been very difficult to immunise in 1925. They had both required two courses of diphtheria prophylactic mixture—six injections of 1·0 c.cm. in all—but were, we think, undoubtedly Schick-negative finally, the boy within two months and the girl within four months of the last immunising injection. We are confident that the toxin dilutions with which these tests were made were of satisfactory potency on both occasions. On retest three years later both children were positive, and after one week and four weeks had no detectable antitoxin in the blood (i.e., less than 1/2000th unit per c.cm.). Schick tests in the first and fourth weeks were also positive. In the fifth week they were given 1 c.cm. of toxoid-antitoxin mixture. Two weeks later the boy had 1/25th unit of antitoxin, indicating a fairly brisk response, but his sister still remained refractory and is receiving further injections.

Discussion.

It will be seen that there is very little difference between the two groups, which can now be considered together for purposes of discussion. At first sight the percentage of children who had reverted to the Schick-positive state after having once been negative is disquieting; 28 children (2·9 per cent.) of 973 who had been read as negative one to seven years previously were regarded as positive on retest. It is, however, reassuring that only four children (0·4 per cent.) required immunising injections, and that three of the four showed a marked rise in antitoxin within one to three weeks of a single dose of prophylactic mixture. It is doubtful, therefore, if the immunising mechanism of these children would really have been sluggish vis-à-vis an average infecting dose of virulent organisms. The fourth child (0·1 per cent. of the entire series) is in a different category, for she failed to show the slightest response to an injection of 1·0 c.cm. of toxoid-antitoxin mixture.

The efficiency of the Schick dose of toxin as a "secondary stimulus" is remarkable. It is a very small amount of toxin, originally founded on 1/50th of the guinea-pig minimum lethal dose, and in combining power is equivalent to 1/1000th of a unit.

of antitoxin. If, however, a Schick-negative reactor has lost some of his antitoxin and becomes Schick-positive, with little or no detectable antitoxin, the Schick dose of toxin may be sufficient to make him once again Schick-negative. In other words, active immunity with the capacity for responding to a fresh stimulus has remained, although circulating antitoxin may have been lost. The fact that a Schick dose of toxin may be capable of stimulating the production of circulating antitoxin in an actively immune subject must be borne in mind in connexion with every type of experiment, in animals as well as in human beings, in which serial Schick tests are used for the study of changes in immunity.

Over and above the series under review we have retested a group of 194 children who were negative on the original test three months previously. All were negative on retest.

The observations, so far as they go, while not completely establishing the dictum "once Schick-negative, always Schick-negative," support the more general statement "once immune, always immune," if by immunity we imply a more ready protective response to the invasion of the specific toxin. One would expect such a "potential" immunity to be sufficient to protect an individual against any serious infection by the diphtheria bacillus.

* = Half a unit of antitoxin per c.cm. of patient's blood.
(a) Further details incomplete.
M = Toxoid antitoxin mixture—1·0 c.cm.
+, ±, −, = Reaction to Schick test.

Summary.

(1) 533 children who were Schick-negative on the original test were retested one to seven years later, and showed a 1·1 per cent. Schick-positive rate.

(2) 440 children who were Schick-positive on the original test were rendered Schick-negative by immunisation. When retested one to seven years later 5 per cent. were found to be positive.

(3) In both these groups nearly all the "relapsed" Schick-positive individuals rapidly produced circulating antitoxin in response to very small amounts of diphtheria toxin, and could be considered as in a state of active immunity.

We have to thank Mr. A. T. Glenny for valuable help and advice as well as for the numerous blood titrations which he has kindly done for us.

THE SCREENED RADON SEED IN THE TREATMENT OF MALIGNANT DISEASE.

BY PHILIP GOSSE, M.D. DURH.,
DEPUTY MEDICAL SUPERINTENDENT OF THE RADIUM INSTITUTE, LONDON;

AND

F. E. CHESTER-WILLIAMS, M.R.C.S. ENG.,
RESIDENT MEDICAL OFFICER OF THE INSTITUTE.

FOR many years attempts have been made to treat tumours by implanting into them small pieces of capillary glass tubing containing radium emanation, but the results of such treatment have been unsatisfactory owing to the necrosis induced by this method, the glass capsule allowing the very destructive β rays to pass into the surrounding tissues.

The use of a capillary seed enclosed in a metal case having attached to it a fine thread has only recently been adopted in this country, though the method has been extensively used in America, particularly by Dr. Joseph Muir, of New York. No statistics of value can yet be given from a series of patients treated with seeds at the Radium Institute, London, but the results which are being obtained are encouraging, more especially in those cases which past experience has shown respond poorly to other forms of radium therapy. The object of this paper is to indicate the type of case most likely to derive benefit from this particular method of radiation and to give a brief description of the apparatus employed at this Institute.

Apparatus.—The seeds are cylindrical shells of platinum tapered at both ends, encasing a piece of capillary glass tubing containing radium emanation. Each seed is 6 mm. long and 1·1 mm. in diameter, having a wall of 0·3 mm. of platinum. Attached to the seed is a fine black thread which serves the dual purpose of marking the position of the seed in the tumour and facilitating its removal when the required dose has been given.

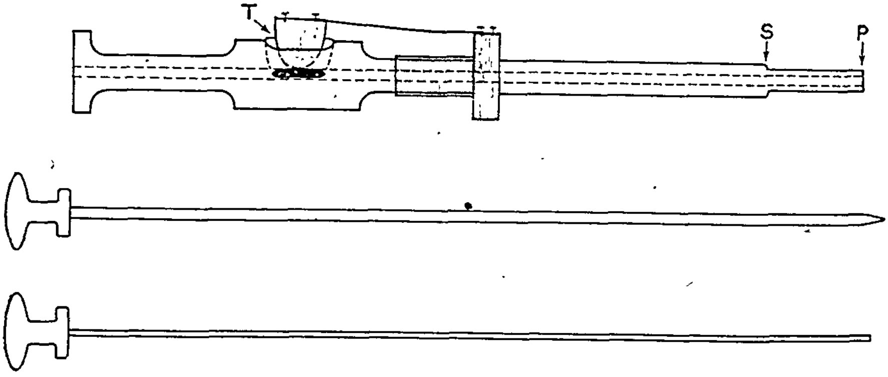
Dosage.—The majority of the patients have been treated with seeds each containing 1·5 millicuries of radon at the time of implanting, giving 200 millicurie hours of radiation if left in the tumour 14 days, by which time its radio-activity is negligible. The platinum screen 0·3 mm. in thickness allows about 90 per cent. of the gamma rays to pass through with less than 5 per cent. of beta rays.

Technique.—A trocar, with a special cannula as shown in the diagram, is used for implanting the seeds. The instrument having been loaded with a seed through the slot T it is inserted into the tumour up to the shoulder S. On withdrawal of the trocar the seed is forced into the lumen of the cannula by the spring and may then be pushed into the tissues with the stilette. It is a point of importance that the use of "introducers" with known but varying lengths from point P to shoulder S, enables the operator to plant seeds at known depths from the surface. As a general rule the seeds in a tumour should be about 2 cm. apart. Seeds may be implanted into tumours of the bladder through an operating cystoscope, using flexible introducers, and special instruments have been devised for use through the œsophagoscope and the proctoscope.

After-treatment.—The threads of seeds introduced anywhere in the buccal cavity may be bunched together, brought out through the mouth, and fixed to the skin of the cheek with adhesive plaster. Experience has shown, however, that patients tolerate the presence of the threads better if they are cut short (½ inch) and left free. While it is customary to remove the seed by gentle traction on the attached thread when its period of activity is over, no ill-effects have been noted in cases where the seeds have been left permanently in the tissues.

Advantages of the Method.

The advantages of seeds over other forms of radium applicators are: 1. By suitable spacing of the seeds throughout the whole tumour a uniform radiation is obtained. 2. The seeds are easily introduced and can be accurately placed in position. 3. Owing to their small size they are retained at the required site. This is of particular advantage in regions where the soft tissues are scanty—e.g., the alveolar margin. 4. Screened seeds without threads may be used in the treatment of tumours from which the recovery of radium needles would be difficult. 5. Patients are not confined to bed throughout treatment, but are able to attend as out-patients for regular examination. 6. Some hours after the insertion of radium needles into tumours of the tongue, for example, it is a common experience to find the heads of the needles becoming exposed, however completely they may have been buried at the time of operation. This is probably due in part to the movement of the tongue and in part to the traction of the heavy silk threads attached. Burns of the mucous membrane of the buccal cavity are likely to result unless special shields covering the alveolar margins and cheeks are employed. Seeds by remaining completely embedded in the tissues minimise the risk of burns and make the use of the cumbersome screens unnecessary. 7. Trauma is minimised, the seed causing little damage to the tissues both at the time of insertion and removal, owing to its size and shape. This is an important factor when dealing with malignant disease.



Cannula, trocar, and stilette, used for implanting radon seeds.

Types of Cases most Suitable for Seed Treatment.

While most malignant tumours may be treated as satisfactorily with seeds as with other forms of apparatus, their use at the Radium Institute has been confined to tumours which, owing to their position, would not receive uniform radiation by other methods.

These may be divided into two main groups. In the first are placed tumours where the retention of radium needles is difficult owing to the constant and unavoidable movement of the structures or to the small amount of soft tissue present. Examples of such tumours are those of the palate, the floor of the mouth, gums, frænum of the tongue, mucous membrane lining the cheek, tonsil, larynx, and pyriform fossa. Into regions such as these it was customary to insert comparatively large doses of radium to act for a short time. This method gave non-uniform radiation, sometimes followed by severe reaction and sloughing. Seed treatment of such patients gives them the triple advantage of a minimum of discomfort, uniform radiation, and a comparatively small dose of radium acting over a period of many days.

Into the second group may be placed tumours whose inaccessibility makes both the inserting and recovering of radium needles a difficult and frequently hazardous undertaking. It is unnecessary to give a list of these tumours which would include such commonly occurring ones as carcinoma of the œsophagus, stomach, prostate, rectum, and bladder. By employing suitable introducers radon seeds may be implanted into most of these, thus ensuring their complete radiation.

Mention must also be made of the suitability of seeds for the treatment of small malignant nodules. The small size of the seed enables it to be completely embedded at the site required. Needles inserted into such nodules frequently cause damage to the surrounding tissues which receive rays from the projecting ends, while small surface applicators are unlikely to remain in the required position for prolonged periods.

While this paper has been devoted to the description of treatment with seeds alone, we have frequently found them of use in conjunction with other forms of radium apparatus.

Illustrative Cases.

The following cases, in which the diagnosis has been confirmed by section, illustrate the results which are being obtained after treatment of the primary lesion with radon seeds.

CASE 1.—*Surface epithelioma,* with little surrounding healthy tissue. Male, aged 61, Treated June 19th, 1928. Fungating epithelioma of the right ear. 3·0 cm. in diameter, growing for two years. Four seeds were inserted into the tumour and left there for six days. Present condition: tumour no longer present, ulcer healed.

CASE 2. *Carcinoma; floor of mouth.*—Male, aged 59. Treated in May, 1928. Patient had a malignant ulcer of the floor of the mouth, which had been noticed for about three months. The ulcer, which had hard edges, extended from the mid-line, backwards beneath the tongue on the left side for about 4 cm. Ten seeds were inserted and allowed to remain for seven days. Present condition: ulcer is completely healed. Movements of the tongue are free.

CASE 3. *Carcinoma of alveolar margin.*—Male, aged 70. Treated January, 1928. Patient had been unable to wear his lower denture during the latter part of 1927. He was found to have a hard, coarsely papillated carcinoma on the alveolar margin of the right lower jaw. Four seeds were inserted for 14 days. On examination in March active disease was noted at each end of the area treated on his first attendance. Four seeds were again inserted. Present condition: a smooth white scar, soundly healed.

CASE 4. *Carcinoma; frenum of the tongue.*—Male, aged 56. Treated March, 1928. This patient had a large carcinomatous ulcer in the mid-line beneath the anterior part of the tongue, spreading on to the floor of the mouth and on to the alveolar ridge. Nine seeds were inserted for ten days. Present condition: soundly healed, no sign of disease.

CASE 5. *Epithelioma of mucous membrane lining the cheek.*—Male, aged 70. Treated April, 1928. Patient had a soft plaque with a velvet-like surface on the buccal mucous membrane of the right side of the mouth. The diseased area was 3·0 by 2·0 cm. in size with little surrounding infiltration. Six seeds were inserted for ten days. Present condition: no evidence of disease.

CASE 6. *Epithelioma of mucous membrane of cheek and gum.*—Male, aged 84. Treated January, 1928. On examination this patient was found to have a malignant ulcer with indurated edges and base, involving the right alveolar ridge and spreading on to the mucous membrane of the right cheek. Five seeds were implanted and removed 14 days later. Present condition: no sign of disease in the mouth.

CASE 7. *Sarcoma of tonsil.*—Female, aged 73. Treated February, 1928. This patient had a firm, smooth swelling in the left tonsillar region, which had been noticed for three months. Six seeds were implanted. Three were recovered 14 days later and three remain permanently in the tissues. Present condition: tumour has entirely disappeared. Mucous membrane is intact.

CASE 8. *Carcinoma of palate.*—Male, aged 60. Treated June, 1928. This patient was found to have an ulcer covered with slough, involving the whole of the soft palate, and extending forwards on to the hard palate. Ten seeds were inserted for 14 days. Present condition: after a very brisk reaction the ulcer is now almost healed.

CASE 9. *Carcinoma of pyriform fossa.*—Male, aged 52. Treated April, 1928. This patient, who had experienced some dysphagia for six months, was found to have a large fungating growth of the pyriform fossa, obscuring the cords. Five radon seeds were inserted for five days. He was examined again at the end of June. His symptoms had been relieved and the growth had shrunk to about one-third of its original size, the left cord, and part of the right, being visible. Five seeds were again inserted and left for 14 days. His first dose of radon was a small one owing to the possibility of acute œdema and obstruction.

CASE 10. *Carcinoma of bladder.*—Male, aged 54. Treated March, 1928. The patient complained of hæmaturia which started in January, 1928. On examination he was found to have a large infiltrating growth on the right side of the base of the bladder. Eleven seeds were inserted into the tumour. Present condition: satisfactory; patient has no further symptoms, and all bleeding has ceased.

CASE 11. *Epithelioma of anal canal.*—Male, aged 54. Treated December, 1927. This patient had a hard, craggy, ulcerated growth encircling the anal canal immediately within the anal sphincter. Pain and the passage of blood per rectum were prominent symptoms. Twelve seeds were inserted through the skin and left in the tissues at the periphery of the growth. On examination three months later no tumour could be detected. The pain and hæmorrhage had ceased.

Seeds have been successfully planted into growths of the œsophagus, but sufficient time has not yet elapsed to enable an opinion of the value of the method to be given.

General Conclusions.

1. The initial response of the tumour is more rapid than that seen with other forms of radium therapy. (2) The local reaction is brisk in some instances. (Another series of patients is now being treated with more heavily screened seeds.) (3) Owing to the very small size of the seed in proportion to the dose of radium it contains, there is a tendency on the part of the surgeon to implant the seeds too close together, and this over-radiation may possibly account for the severe reaction occasionally met with. (4) The use of seeds enables those tumours, which owing to their nature or position are difficult to treat by other methods, to receive thorough radiation.

We wish to express our gratitude to Mr. W. Lester Alton, physicist at the Radium Institute, and to his assistant, Mr. A. E. Southon, for their helpful advice and skill in the preparation of the apparatus.

THE BROMSULPHALEIN TEST OF LIVER FUNCTION.

By ERNEST BULMER, M.D., M.R.C.P. EDIN., M.R.C.P. LOND.,

ASSISTANT PHYSICIAN, GENERAL HOSPITAL, BIRMINGHAM.

ABOUT 18 months ago my experiences of this test were published, and they were distinctly unfavourable, as a number of normal cases gave abnormal results, and even in cases of definite liver disease 20 per cent. of the readings were at variance with the clinical evidence.[1] For this series a bromsulphalein was made in this country, on the lines of statements made by Rosenthal and White in the *Journal of Pharmacology and Experimental Therapeutics* in 1924. It was subsequently found that this dye differed in certain particulars from that of Rosenthal and White, and in consequence did not give results representative of liver efficiency. Bromsulphalein is, at any rate at present, a proprietary obtainable only from Hynson, Westcott, and Dunning, of Baltimore. I am indebted to them and to Dr. White for having sent me the dye for use in this new investigation. The results are set out below, and they are a contradiction of the previous ones published.

A review of the history of the test was given at some length in a previous paper,[1] and only a few salient points need to be repeated. Bromsulphalein or phenoltetrabromphthalein sodium sulphonate was prepared by White; it is a whitish powder very freely soluble in water, and it can be given with impunity by intravenous injection in a concentrated solution. It is non-irritant, and in ordinary doses absolutely non-toxic. Normally the dye is seized by the liver, and the majority is excreted in the bile, traces only appearing in the urine. The rate of disappearance of the dye from the blood serum is important—after five minutes 20–50 per cent. remains in the blood, whilst at the end of half an hour there is none at all or a mere trace. It was argued that if the liver were damaged it would remove the dye with less rapidity from the blood after injection, and that the degree of retention of dye in the blood stream would give an indication of the degree of liver damage; the originators of the test, Rosenthal and White,[2,3,4] denied that it had any dependence upon biliary permeability.

Technique.

The patient is weighed and the dosage is calculated on a basis of 2 mg. of the dye per kilo body-weight—the body-weight of the patient *in pounds divided by* 55 will give the exact quantity in cubic centimetres of the 5 per cent. solution employed. It is injected slowly into one of the arm veins. Thirty minutes after the injection a sample of blood is withdrawn, preferably from the opposite arm, and in cases of early liver disease it may be necessary to take a sample after five minutes. After the blood has coagulated it is centrifugalised and the clear serum is pipetted into two small test-tubes. To one of these is added one or two drops of a 10 per cent. solution of sodium hydroxide to bring out the colour of the dye, and to the other tube a drop of 5 per cent. hydrochloric acid to clear the serum of any hæmolysis. The amount of dye in the serum is now estimated by direct comparison with a series of standards, using a simple comparator box in the usual way. The standards may be prepared by adding 4 mg. of the dye to 100 c.cm. of water that has been alkalinised with 0·25 c.cm. of a 10 per cent. solution of sodium hydroxide. This represents the 100 per cent. standard, and a series is prepared ranging from 5 per cent. upwards by dilution with alkaline water. In practice it is much simpler to employ the series of non-fading standards prepared by Hynson, Westcott, and Dunning. The 100 per cent. standard represents the amount of the dye that would be present in the blood stream if none were removed: it is thus an arbitrary standard calculated on blood volume.

Clinical Findings.

(*a*) Rosenthal and White[4]:—

	Cases.	Retention expressed in percentages after 30 minutes.
Non-liver	25	0 or a mere trace.

Cardiac liver — moderate jaundice.	1 ..	18.
Non-calculous cholangitis with *intermittent* painless jaundice for 2 years.	1 ..	30 (11/8/27), 30 (3/9).
? Pancreatic calculus ..	1 ..	0.
Acholuric jaundice with cholelithiasis.	1 ..	12.
Tested during N.A.B. treatment—no symptoms.	2 ..	10 (last injection 14 days before); 0 (2 days *before*).
Congenital chorea ..	1 ..	0.
Primary cancer of liver without jaundice.	1 ..	5.

During the administration of choriotrope three cases were tested :—

1. *35 c.cm.* given, the last dose being 18 days before the test and followed by jaundice—now clear. 40 per cent.
2. *15* c.cm. *given,* the last one month before the test. 0 per cent.
3. 33 c.cm. given, the last ten days *before the test. 0 per cent.*

Two of these cases require a little amplification; the fifth case of N.A.B. jaundice showed a very much greater retention after a period of treatment than before it (105 per cent.); she was clinically improved, however. A possible explanation is that the injection was given into the same vein from which blood was later withdrawn; it is probable that the sample was thus accidentally contaminated with dye from the skin or from the vein. One of the cases of cirrhosis was admitted to hospital for a painless hæmatemesis, a bromsulphalein test showed merely a faint trace of dye after half an hour; at operation later a definite early cirrhosis of the liver was found. There was no reason to suspect a sufficient degree of functional incompetence to produce any dye retention.

Conclusions.

1. Normal cases and those without any liver lesion showed a retention of 5 per cent. to a mere trace or even no dye at all.

2. Cases of liver disease showed a retention which probably represented fairly accurately the degree of liver damage or functional impairment; 100 per cent. retention means that no dye is removed from the blood, and a retention of, say, 50 per cent. would mean that the liver was 50 per cent. incompetent, and so on.

3. The test is one of liver function and not of biliary permeability; this is proved by the fact that many of the cases of complete obstructive jaundice did not give a 100 per cent. retention.

4. The test is safe, simple, and it appears to be the best one we have.

Finally, the writer would like to express his thanks to the honorary medical and surgical staff of the General Hospital, Birmingham, for their kindness in giving him access to their cases.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are some of the 1927 statistics of seven districts :—

Name of district and estimated mid-year population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Diarrhœa, &c., under 2 years.	Maternal mortality from childbirth.
Grimsby C.B. .. (88,340)	18·7	11·7	1·19	1·38	2·4	1·4	66/29	5·4	3·7
West Bromwich C.B. (81,140)	20·2	12·4	0·66	0·97	4·7	1·3	107/43	14·6	2·4
Carlisle C. and C.B. (56,620)	18·3	12·3	1·09	1·39	2·4	1·6	68/24	8·7	2·9
Eastbourne C.B. (56,710)	11·5	11·5	0·80	2·0	1·7	1·9	44/18	1·5	4·6
Tunbridge Wells B. (33,870)	12·8	15·7*	0·68	2·26	3·1	3·0	48/23	0·0	4·6
Leamington Spa B. (30,050)	13·5	14·1*	0·99	1·69	2·7	2·4	69/42	7·3	4·9
Colchester B. .. (45,170)	15·6	11·2	0·75	1·46	1·9	1·9	46/—	1·3	5·3

C.B. = County Borough. B. = Borough.

* Health resorts, by attracting as residents old people and invalids, swell many of their death-rates. Thus the death-rates from all causes of Tunbridge Wells and Leamington Spa, when standardised for age and sex constitution of the population, become 11·5 and 10·74 respectively. The contrast between the infant and neonatal mortality-rates of the three health resorts shown above is very striking.

Grimsby.

Dr. B. C. Stevens reports that the municipal maternity home, with ten beds, erected on the council's housing site at Nunsthorpe, was opened for the admission of cases on Sept. 19th. Dr. Stevens thinks it will soon need enlarging. Seven notifications and six deaths from encephalitis lethargica were recorded during the year. The notification of tuberculosis is still not nearly so complete as it might be. Of the 105 total deaths, 24 were of cases not previously notified, and only 29 lived for six months after notification. Insufficient institutional accommodation has been some excuse for incomplete notification in the past, but a scheme now under consideration for the extension of treatment facilities ought to meet this objection. Another feature of the work that requires development is the examination of contacts. At present the staff is insufficient for the visitation of homes for this purpose, and home visitation is considered by Dr. Stevens essential for the full development of examination of contacts. A combined clinic supplies artificial light treatment for the dispensary, the infant welfare centres, and the schools. "On the whole the results have been very encouraging and have amply repaid the expenditure." The total cases treated at the V.D. clinic during the last six years have been 1206, 827, 437, 465, 480, and 533, and the defaulters—that is, those who ceased to attend before being cured—for the same years numbered 547, 479, 184, 93, 89, and 79. Dr. Stevens advocates the establishment of a centre where persons, who have exposed themselves to the risk of contracting venereal disease, can be immediately disinfected by a skilled orderly. He thinks a capital expenditure of £100 or a weekly expenditure of £4 would be ample for the purpose, and that such a scheme would save money by lessening the need for treatment. The causes of the six maternal deaths were puerperal sepsis 2, antepartum hæmorrhage 1, post-partum hæmorrhage 1, and eclampsia 2. The midwives realise the importance of the antenatal supervision put upon them and are referring more cases to the antenatal clinic. The new cases at this clinic numbered 205, the total births being 1624.

West Bromwich.

Dr. W. Stott reports that in September it was decided to reorganise the health visiting staff and to replace the part-time nurses from the district Nursing Association by six newly appointed health visitors, who began their duties on Nov. 1st. The area of the borough is now divided into eight districts, and one nurse is responsible for all the health visiting services in each district. The medical staff has unfortunately been reduced from three to two. As a result it is impossible for the doctor to examine all the children brought to the centres, and it is also impossible to undertake antenatal and postnatal work. The outstanding feature of 1927 was the large number of deaths of children from pneumonia, caused by the prevalence of measles, whooping-cough, and influenza during the first quarter. Dr. Stott advocates provision for the home nursing of measles, whooping-cough, and pneumonia, with hospital accommodation for severe cases, and he further suggests that the first cases of measles or whooping-cough in children under 5 should be made notifiable. The instruction to the midwives to do antenatal work is receiving attention, but renders the provision of an antenatal clinic all the more urgent. Seventy-five stillbirths were notified in 1927 as against 58 in the previous year. There is, as yet, no definite orthopædic scheme, no scheme for the home nursing of children under 5, no minor ailment clinic in connexion with the welfare centres, and no dental treatment included in the maternity and child welfare scheme. Of the 46 deaths from pulmonary tuberculosis 10 were those of cases unnotified, and of the 8 non-pulmonary tuberculosis deaths 6 were those of unnotified cases. The sanitary inspector, Mr. H. H. Spears, after comparing the results of last year's housing inspections with those made of the same houses six and seven years previously, finds "that notwithstanding the general housing activities of the council, conditions as regards two-family occupation and overcrowding in such houses have in no wise improved." The new houses erected during the year numbered 466 and included 286 municipal houses. In a few outlying districts there are still some surface wells in use, and Dr. Stott refers to one used for the supply of three farms, which is liable to pollution by the overflow of the river. The opening of the new Health Department building in December will greatly facilitate the work.

Carlisle.

Dr. Joseph Beard says that the report calls for little comment and that the sanitary condition of the city generally may be said to be good. Out of 20 samples of fresh cow's milk two contained tubercle bacilli, resulting in the eliminiation of one milch cow from the city byres and of two outside cows from a herd in the Longtown area. The Ministry of Health have sanctioned 1728 municipal houses, 1540 "non-parlour" and 188 "parlour." Of these, 1394 have been completed and the remaining 334 were in course of erection at the end of the year. Dr. Beard complains that notification of tuberculosis is frequently so late as to be useless. During 1927 about 18 per cent. of the deaths were those of unnotified cases. A further 8 per cent. of the deaths occurred within one week of notification, while only 37 per cent. survived notification by more than three months. During 1926 the town clerk drew the attention of the medical men of the city to this failure to notify. The register of cases was completely revised during the year and now includes 145 males and 141 females of the pulmonary type and 46 and 47 respectively of the non-pulmonary type. This gives a total of 379, or about six times the average annual deaths during the last six years. Considerable difficulty is experienced in obtaining a satisfactory examination of contacts, but there is some improvement with regard to children. During the year the practising midwives attended 382 confinements and sent for medical help in 120, or more than 30 per cent. of their cases. The antenatal clinic was attended by 185 mothers who paid from three to four visits each; the total births numbered 1037.

Eastbourne.

Dr. W. G. Willoughby reports that 405 houses were erected during the year, of which 198 were municipal and 45 subsidised houses erected by private enterprise. No houses at low rents have been built recently except by the municipality, but houses at as low a price as £700 have been built for sale. The council assisted the private purchase of houses in 78 instances during 1927, making a total of 260 houses so dealt with. The temporary army hutments have been reduced from 188 tenements to 36 and the last 36 tenants are difficult to deal with, but "it is time that these huts should be totally demolished." The lowest rents for municipal "non-parlour" houses are 14*s*. 6*d*. weekly. The total of municipal houses occupied and planned is 723, but building for yearly needs must go on, says Dr. Willoughby, and particularly for those who canont afford the rent mentioned. Of the 764 applicants for new houses 90 have a whole house at present, 99 are newcomers, and 109 live outside the borough. Of the remaining 466, who have been in the borough more than five years, 78 have no child, 200 have one child only, and 89 have at least three rooms each. Dr. Willoughby estimates that there are at least 200 to 250 good tenants in a difficult position. There is too much sharing and subletting of houses, and many of the applicants would like a smaller house at a lower rent. Some of the municipal tenants have caused overcrowding by subletting. The municipal maternity home (ten beds) has been improved by the provision of extra accommodation for the staff and of facilities for antenatal work. The orthopædic clinic is run by a voluntary association for whom the local authority provides a consultant. An enclosure on the sea front, in connexion with it, allows sun treatment to be provided for children in the summer. Dr. Willoughby states that the regulations for the protection of meat have almost no practical effect owing to the restrictions involved. The majority of meat vendors object to sheltering the meat behind closed windows. Dr. Willoughby disagrees with those who favour the shortening of the stay of scarlet fever patients in hospital. The revision of the tuberculosis register has reduced the cases to 318 which is about seven times the tuberculosis deaths for 1927. The rainfall for the year was 38·22 in. The sunshine record, 1698·8 hours, was the fourth highest recorded in the United Kingdom, excluding the Channel Isles and Scilly Isles.

Tunbridge Wells.

Dr. F. C. Linton says that apart from a sharp outbreak of influenza in February involving temporary school closure and causing many deaths amongst old persons, there was no notable outbreak of infectious disease during the year. The municipality works chiefly by subsidising voluntary institutions. Since April 1st, 1928, an agreement has been made for the treatment of children by massage, exercises, electricity, &c., at the clinic established at the general hospital. The district Nursing Association is subsidised for the home nursing of children and for the provision of a nurse-midwife in Rusthall. Payment is made by fees to various hospitals for the treatment of tonsils and adenoids. An arrangement has been made with the maternity home for the admission of municipal cases and three cases were sent in in 1927 where the mother's home environment was unsatisfactory and her circumstances needed financial aid. A chart shows that diphtheria was exceptionally prevalent from 1896 to 1900 and again from 1911 to 1915. Dr. Linton argues from these figures that the disease should be rife from 1926 to 1930 and in accordance with his prediction the notifications rose to 42 in 1927, after an average of about 12 for the four preceding years. There was only one death. The school report shows that the question of an open-air school for 40 children has been advanced a stage further by the raising of £1000 by voluntary contributions. Dr. J. A. Walker Wood began work as aural surgeon in the schools in April, 1927. The rainfall was 40 in. and the hours of bright sunshine 1527⅔.

Leamington.

Dr. W. L. Goldie reports that the baths have been rebuilt and now compare most favourably with those of any spa in the country. A new scheme of filtration has been installed for both the men's and women's swimming baths. The total number of council houses was brought up to 286 by the erection of 83 during the year. There were 12 subsidised private enterprise houses. The "Leamington Slum Clearance" Company built eight houses at Lillington which were intended to be let at an inclusive rental of 5s. a week, but were ultimately let at 10s. An agreement has been made with the Warneford Hospital for the subsidisation of three maternity beds. Mr. G. C. Alderson, who is in charge of the obstetric department of this hospital, conducts an antenatal clinic for the patients seeking admission to the hospital, and he has been appointed specialist for the purpose of the Puerperal Fever Regulations. The rainfall was 28·84 in. and the record of bright sunshine 1121·7 hours.

Colchester.

Dr. W. F. Corfield gives a table, which shows that 24 of the 35 infant deaths were due to congenital debility and premature birth. He hopes that the work of the antenatal centre begun in March, 1928, will help to reduce this figure. The deaths of children during the first year of life numbered 35, during the second year 14, and of those from 2 to 5 years 13. An effort is being made to find suitable premises for a maternity home, but so far unsuccessfully. The orthopædic clinic is doing good work and treated 17 infants as compared with 9 in the previous year. A difficulty has arisen with the local division of the British Medical Association with regard to the appointment of a consultant for the purpose of the Puerperal Fever Regulations. During the year 192 subsidised houses were built, 106 municipal and 74 by private enterprise. Reports of overcrowding are still received and there is need of accommodation for the poorest working-class families. Unfortunately a large number of families have to live in two rooms or even one room owing to the cost of housing accommodation. During the past years there has been much building of new houses in the outskirts. This is being now followed by the extension of water mains and sewers, which should ultimately enable shallow wells to be closed and cesspools to be abolished. During 1927, however, 19 new cesspools and 7 new wells were constructed. About 550 "hand-flushed" closets have been provided with a water-supply during the last three years.

SCHOOL MEDICAL SERVICE.

Name of district.	No. on roll.	Aver. elem. school attendance.	No. of routine children examined.	No. of special examinations and re-inspections.	Percentage of children found on routine examination requiring treatment.*
Northampton C.B.	12,352	11,107	3,432	7,687	18·7
Bournemouth	7,984	6,796	2,160	3,952	14·0
Hull	47,517	38,614	17,075	34,719	15·8

* Excluding uncleanliness and dental defects.
C.B. = County Borough.

Northampton.

It would, we think, be admitted that the extent of the facilities for preventing and treating childish defect and disease is a fair measure of the interest taken in child hygiene by any community. Judged by this standard Northampton comes out badly, for in this county borough even the routine inspections cannot be overtaken by the school medical staff, and much of the value of their work is necessarily lost. Dr. Stephen Rowland, in his introduction to the report by Dr. J. H. Mason, says he does not think that the two sessions per week now given by the assistant tuberculosis officer will be sufficient to keep pace with the work; he does hope, however, that the arrears in dental treatment will be made up by the second dentist now appointed. Dr. Mason, who until last October carried out the school medical work single-handed, draws attention to the large number (246) of delicate, anæmic, and debilitated children who would benefit by the régime of an open-air school. Dr. Rowland is "not convinced that the so-called 'open-air school' is much in advance of the latest elementary schools opened in Northampton." He does not describe the conditions of these new schools, but it would seem that a properly constituted open-air school, with a specially designed curriculum, where there is fuller medical supervision, extra rest, suitable meals, and out-of-doors lessons and games, is more suited to the needs of a delicate child than even the most modern elementary school where the curriculum and routine work are arranged for the average healthy normal child. It is often the endeavour to keep pace with his more lusty fellows that pushes the delicate child over the brink of definite ill-health. Dr. Mason describes the work done in Wellington-place Special Mental Defective School, opened in 1907, and supervised from its inception by Miss Longland, who also acts as secretary to the committee of voluntary workers which looks after the welfare of past pupils. In all, 234 children have passed out, of whom 24 are dead, 101 are either in institutions or not in work, and 109 are partially or wholly self-supporting. Whatever the future may hold in the way of prevention or of treatment of mental defectives, it is certain that the discipline, interest, and self-respect instilled by the simple manual occupations at present taught in the special schools is well worth the cost, for if these unfortunates are left unheeded they become a greater burden on the community.

Bournemouth.

Dr. T. S. Stirling remarks that the general work of medical inspection is progressing satisfactorily, and notes a continued improvement in the standard of personal hygiene due to the work of the school nurses, aided by lending out, if required, of special combs with a leaflet of instruction. The dental work has been efficiently carried out, but there is still a long list awaiting treatment, and the pre-school child must not be forgotten. Dr. Stirling says that in this, as in many of the other defects and diseases of childhood, preventive treatment should be attempted at an earlier age; this, with a suitable physiological diet in infancy, will lessen the prevalence of dental caries in school children. The idea of the special class for backward children was to return these children after a course of 6 to 12 months to their own school with a reasonable expectation of making normal progress; this has not been realised, though the children have derived benefit, especially physically. Probably there are in this class all three types of retarded children—namely: (1) The true backward, that is those who have merely lost education time through being handicapped by disease or physical defect, and thus need a recovery class; (2) the true dull, those who are mentally slow and better with concrete material, and thus need a handicraft class; (3) the true mental defective, mentally lacking in all kinds of intelligence, needing training in concentration, stabilising in temperament, and some degree of care, control, or supervision in after-life. The formation of even this one experimental class is of value, especially as it is a small one with only 15 children, so that an energetic teacher will try to group the children for herself. It is, however, regrettable that there are no special schools and particularly no open-air school, for there are in Bournemouth 246 delicate children with whom results could be obtained comparable with the splendid record of many similar towns.

Hull.

Dr. W. Allen Daley deals with important schemes of reorganisation, details of which are given by his chief assistant, Dr. J. Morrison. Routine examinations have increased from 15,526 in 1926 to 17,075. The standard of marking for defects has been made slightly more stringent, to bring it into line with that of other authorities; thus the percentage of defects this year amounts to 15·8 compared with 10·5 in 1926, although the actual numbers of defects have probably not increased. Special inspections show a great increase as the result of the new scheme by which teachers send children to the medical officer at a school clinic, instead of waiting for a routine visit to the school. Treatment at the clinics has been greatly expanded —6200 minor ailments were treated this year as against 3281 in 1926. X ray treatment for ringworm will in future be given by the two newly appointed radiologists. In dental treatment there has also been a reorganisation of the scheme, including an extension to include the 5-year-old group, increased general facilities with the appointment of an additional dentist, and the elimination of casual cases, which are very unsatisfactory. There are, further, some new activities at the clinic; those of the aural surgeons, Mr. T. Ritchie Rodger and Mr. R. R. Simpson, whose expert opinion is found so valuable in cases of tonsils and adenoids, and of the orthopædic clinic just started under Mr. R. B. Blair. This orthopædic clinic deals also with cases referred by other departments—the general public health, the tuberculosis, and the maternity and child welfare.

The planning of this work as regards school-children was temporarily upset by an epidemic of acute poliomyelitis affecting 22 children over 5 years of age, and over 70 below that age. Of the older group one died during the attack, in four cases the paralysis cleared up, and in 17 there remained varying degrees of disability, though, as usual, there was some tendency towards recovery. The younger group is not similarly described, but it is certain, as Dr. Morrison says, that the epidemic will leave lasting traces among the school-children of future years. The action taken illustrates very well the advantages of coördination. Many of the victims were isolated and treated in the City Hospital; they were examined by the school orthopædic surgeon, who prescribed the treatment to be carried out both in hospital and after discharge. Later they were taken to the Park Avenue School for physically defective children, where splints were applied when necessary, and appointments made for massage, electricity, or remedial exercises at the orthopædic clinic. In the case of private patients, letters were sent to the doctors offering facilities for treatment at the orthopædic clinic, which was in the majority of cases accepted. Two recently appointed orthopædic nurses carry out this treatment at the clinic under the supervision of the surgeon. Minor postural deformities are reported to the organiser of physical training for special exercises to be given at school.

Another important step has been taken in the new practice of examining mentally all the children admitted to the craft classes, thus raising these classes to their proper function of dealing with the concrete minded children, who are intelligent enough but not literary, instead of allowing these classes to become the dumping ground for all types of retarded and defective children. The whole report shows evidence of a highly efficient staff working with an enlightened local authority.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED AUGUST 4TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 126 (last week, 149); scarlet fever, 1461; diphtheria, 882; enteric fever, 277; pneumonia, 526; puerperal fever, 39; puerperal pyrexia, 85; cerebro-spinal fever, 7; acute poliomyelitis, 2; acute polio-encephalitis, 2; encephalitis lethargica, 28; dysentery, 7; ophthalmia neonatorum, 139. No case of cholera, plague, or typhus fever was notified during the week.

A large proportion of the cases of enteric fever were notified in London and the home counties, viz.: London 87 (of which 26 in Kensington, 17 in Wandsworth); Buckingham, 4; Essex, 5; *Hertford*, 7; Kent, 7; Middlesex, 25 (of which Ruislip-Northwood 6); Surrey, 97 (of which Beddington and Wallington 24, Epsom 23, Sutton and Cheam 10, Epsom Rural 18). The 277 notifications included 175 cases of paratyphoid fever, of which 60 were notified in London, 83 in Surrey, and 11 in Middlesex.

The number of patients in the Infectious Hospitals of the Metropolitan Asylums Board on August 7th–8th was as follows:—Small-pox, 17 under treatment, 1 under observation; scarlet fever, 1706; diphtheria, 1681; enteric fever, 72; measles, 263; whooping-cough, 187; puerperal fever, 14 (plus 9 babies); encephalitis lethargica, 71; poliomyelitis, 2; "other diseases," 15. At St. Margaret's Hospital there were 17 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 3 (2) from enteric fever, 21 (2) from measles, 2 (2) from scarlet fever, 36 (4) from whooping-cough, 29 (5) from diphtheria, 50 (14) from diarrhœa and enteritis under two years, and 16 (4) from influenza. The figures in parentheses are those for London itself.

The fatal case of enteric fever outside London was reported from Edmonton. Of the 19 fatal cases of measles outside London, 6 were reported from Liverpool and 3 from Newcastle-on-Tyne. Belfast reported 5 in the same week. Of the 32 fatal cases of whooping-cough outside London, 7 were reported from Birmingham, 4 from Manchester, and 3 from Liverpool. The deaths from diarrhœa showed no increase.

The number of stillbirths registered during the week was 295 in the great towns (corresponding to a rate of 41 per thousand births), including 43 in London.

THE PROCEEDS OF HOSPITAL FÊTES.—During the last eight years. Hendon Cottage Hospital has received £7287 as the proceeds of an annual fête. This year's event resulted in a profit of £1050.

TRAUMA AND COMPENSATION IN OBSTETRIC AND GYNÆCOLOGICAL CASES.

By DOUGLAS MARSHALL LINDSAY, M.D., F.R.F.P. & S. Glasg., Senior Assistant Visiting Surgeon, Royal Samaritan Hospital, Glasgow. London and Edinburgh: William Hodge and Co., Ltd. 1928. Pp. 172. 7*s.* 6*d.*

THIS book is a useful contribution to a subject either cursorily dismissed or not considered at all in obstetric and gynæcological treatises. Yet, as the author points out, application for damages is very common among women, and real or fancied injury to a pregnancy offers "a good background for the staging of a case before an impressionable jury." The number of cases quoted from Dr. Lindsay's own experience serves to show both the frequency of claims of this kind and the solid foundation of practical knowledge on which this book is built. The instructions as to methods of examination, the way to record findings, and the precautions to be taken when giving an opinion are excellent.

Concerned, as it is, with a very special side of obstetric and gynæcological practice, this book may not appear to be of general interest, but even a superficial glance reveals many points that have a much wider application than its title suggests. It contains, for example, an excellent review of the diagnosis of pregnancy in which the various symptoms and signs are weighed and the value appraised of those that are of use in estimating the stage that the pregnancy has reached, and in determining the life or death of the fœtus in utero. One sign in the diagnosis of pregnancy, that form of external ballottement known as "dipping" has been overlooked. To many it is the most certain and quickest method of differentiating the pregnant uterus from other cystic swellings at or about the umbilical level and before fœtal parts can be distinctly recognised.

Dr. Lindsay makes a very definite statement that trauma is never a causative factor in the production of a neoplasm; his views on this question are diametrically opposed to those expressed by Dr. Janet Lane-Claypon in regard to injury as an ætiological factor in mammary carcinoma (Ministry of Health Report No. 32). Sarcoma of bone appearing after injury he regards as "having probably been the precursor of the fracture." Whilst refusing to consider a traumatic cause for pelvic growths, simple or malignant, he gives full consideration to the possibility of their being adversely affected by injury, as by the occurrence of torsion, rupture, necrosis, and infection.

The volume has closed a distinct gap in gynæcological literature, and will be found exceedingly helpful to those who have to make frequent appearances in the law courts to give a medical opinion in those compensation cases or actions for damages in which possible pelvic injury to women is in question. The author's experience in obstetrics and gynæcology, and as assistant to the Professor of Medical Jurisprudence in Glasgow, makes his advice of particular value in such cases.

EXPERIMENTAL EMBRYOLOGY.

BY THOMAS HUNT MORGAN, Professor of Experimental Embryology in Columbia University. New York: Columbia University Press. 1927. Pp. 766. 37*s.* 6*d.*

THE introduction of experimental methods, chemical, physical, and physiological, into embryology is an important development. Although such methods have been applied for over 40 years by a few scattered workers and have yielded fruitful results, these results have so infrequently been brought to the general notice that those not intimately familiar with the work have difficulty in correlating them and in appreciating their full significance. Prof. Morgan's book, which is a complete and critical survey of the important experimental researches, will be welcomed. Moreover, it will appeal to a wider section of scientific workers than did the older embryology books, which described the building up of evidence in a chain of pictures revealed by the microscope. The experimentalists have called into play methods more proper to the chemical and to the physiological laboratories. This change of outlook has revealed new lines of attack on the problems presented by each stage in the complicated process of development. The changes which take place in the process of fertilisation of the egg are vast and complex. Already the amount of fruitful experimental research relating to that incident alone, including the questions of the activity, chemotaxis and agglutination of spermatozoa, the fertilisation, membrane and its functions, selective fertilisation, cross-fertilisation, and polyspermy, exhausts eight chapters, or over 100 pages of the book.

The remaining six hundred odd pages are occupied with the questions involved in the changes in cytoplasm prior to cleavage of the cell, and in the movements of groups of cells following cleavage. Such matters as growth, reflex actions, and trophistic movements of larvæ, sex determination, embryonic grafting, the influence of environment on the development of the embryo, and the source of energy of development, are promised for a future volume. The investigations relating to each section are recorded more or less in their chronological order. The author's conclusions, which are restrained and conservative, are inserted into the text at intervals none too frequent. His obvious reluctance to introduce speculative matter might indeed have been modified to the extent of furnishing short summaries at the end of each section, for an historical account of such complex work must necessarily in places be disjointed, calling for effort on the part of any reader anxious to understand the trend and significance of the progress made. However, since Prof. Morgan provides over 2000 references to works on experimental embryology and sets forth concisely and lucidly a description of practically every important piece of work that has been done on the subject, no one need complain.

To workers in every branch of biology who are seeking for a new line of research this book should provide a mine of inspiring suggestions.

ENDOCRINE DISEASES.

Endokrine Krankheiten. By Prof. Dr. HANS CURSCHMANN, Direktor der medizinischen Universitätsklinik zu Rostock I.M. Dresden and Leipzig: Theodor Steinkopf. 1927. Pp. 151. R.M.S.5.

THE series of monographs to which this volume belongs is designed to give a practical survey of the various domains of medicine. Prof. Curschmann's Endocrine Diseases can claim to have fulfilled this object. Controversial matter has been almost entirely ignored, and where theoretical interpretation is still far from clear the author has contented himself with giving the facts and a short allusion to the difficulties. No condition associated with disease of the endocrine system seems to have been omitted. The method of dealing with any particular gland is to give first a short description of its anatomy and physiology, then a detailed account of the symptomatology, pathogenesis, prognosis, and treatment of diseases associated with it. Certain rare metabolic disturbances of uncertain origin are included. For instance, a section is devoted to what is termed endogenous cachexia. This condition is conceived as the clinical antithesis to endogenous obesity. The author differentiates it from a masked hyperthyroidism, in which there are no eye or circulatory disturbances, and from wasting of hypophyseal origin (Simmond's disease). The metabolic rate is not raised nor is the protein metabolism increased, as in Graves's disease, and yet there occurs a progressive loss in weight until the patient becomes a veritable skeleton. The author claims that by psychotherapeutic measures the appetite of these cases can be so stimulated that the weight increases. By doses of insulin up to 20 units daily weight can also be made to increase, but the writer denies that the condition is in any sense of the word a "hypo-insulinism." In view of the most recent work on mongolism it is strange to find this condition included in this monograph; indeed, the author himself, having described the malformation, concludes that there is no evidence of an endocrine dyscrasia. An interesting point in the treatment of exophthalmic goitre is emphasised—the importance of diet. This is a revival of the old view of Blum that the diet should consist of foods containing a minimum of tryptophane, which is the chemical basis of thyroxin. Meats, milk, cheese, eggs, and wheat are rich, whilst maize, rye, potatoes, and fruits are poor in this substance. However, since one of the main objects of treatment is to re-establish nitrogen equilibrium in the exophthalmic patient, it would not be very easy to avoid those foods which are here condemned.

The section on diseases of the sex glands has been written by Dr. F. Prange and is well illustrated. The space allotted to details of treatment in this book is rather scanty, but the general principles which should guide the management of the patient are made clear.

The Clinical Examination of the Lungs.

Second edition. By E. M. Brockbank, M.D. Vict., F.R.C.P.; and Albert Ramsbottom, M.D. Vict., F.R.C.P. London: H. K. Lewis and Co., Ltd. 1928. Pp. 112. 5s.

This book was written for students, and is intended to outline the methods of examining the chest. It is not sufficiently detailed to appeal to the post-graduate student, who would require more detail. After a brief chapter on physiology and anatomy, five chapters are given up to a discussion of the symptoms and physical signs of pulmonary disease, the authors following the orthodox order of inspection, palpation, percussion, and auscultation. The last chapter deals with physical signs of common pulmonary diseases, and this is too sketchy to be of real value even to students. Very little space is devoted to each disease, such a variegated condition as new growth of mediastinum, lung, and pleura being dismissed in six lines. The reader is told that X ray examination is a useful aid to diagnosis in various conditions, but it is not made clear in what way it may help. At the end of the book are eight X ray plates illustrating a normal chest and various pathological conditions. If the volume is regarded as a convenient and clear, but not exhaustive, account of physical signs and symptoms in diseases of the chest it will prove a useful addition to the students' library.

Bacteriology.

Handbuch der Pathogenen Mikroorganismen. Third edition. Edited by Kolle and Wassermann. Revised and enlarged with the assistance of W. Kolle, R. Kraus, and P. Uhlenhuth. Jena: Gustav Fischer; Berlin and Vienna: Urban and Schwarzenberg. 1928.

The new edition of Kolle and Wassermann's well-known text-book upon bacteriology is now in process of making its appearance in instalments; up to the present time 12 parts have been received, representing portions of the ten volumes of which the book will ultimately consist, none of which has yet appeared in its entirety. The wealth of detail is greater than that given in any other work on bacteriology with which we are acquainted; the article on plague, to take a single example, by Dieudonné and Otto, occupies 223 pages and is superbly illustrated. The work is already firmly established as a mine of information upon all the ramifications of bacteriology and immunity. Amongst the subjects dealt with in the parts which we have received are plague; Asiatic cholera, which comprise the whole of one part, a matter of 178 pages; glanders; rinderpest and other special animal infections; diplococcal infections; and a large part of the subjects of general bacteriology, immunity and serology. When complete the book will form a standard book of reference and, meanwhile, has the advantages of a series of monographs, each contributed by an authority in his own special sphere.

Investigation of the Concentration of Lactic Acid in Blood and Urine under Physiologic and Pathologic Conditions.

By Otto Jervell. Acta Medica Scandinavica, Supplementum XXIV. Oslo: Nationaltrykkeriet. 1928. Pp. 135.

This book consists of a collection of researches carried out during the last four years by the author, partly at the Physiological Institute of the University of Oslo, and partly at the Oslo Municipal Hospital. It is divided into three parts: the first, an introduction, deals with previous work and methods of analysis, the second with lactic acid under physiological conditions, and the third with the concentration of lactic acid in the blood in various pathological states. In the first part some six pages are devoted to a very brief review of the work, beginning with that of Fletcher and Hopkins in 1907, which deals with the rôle of lactic acid in the metabolism of carbohydrates. Dr. Jervell then proceeds to describe the method used by him for the estimation of lactic acid in blood and urine. In the case of blood, the proteins are first precipitated by tungstic acid, as in Clausen's method, using 2 c.cm. of blood. The glucose, together with a part of the uric acid, is then removed from the filtrate by the use of copper sulphate and calcium hydroxide. The estimation is performed upon the filtrate from this precipitation by Hansen's method, which involves the oxidation of the lactic acid to acetic acid and carbon dioxide by a measured excess of potassium dichromate solution and sulphuric acid. The unused dichromate is afterwards estimated iodimetrically. When lactic acid in urine is being determined, it is necessary first to extract the lactic acid by means of ether, using Clausen's apparatus for this purpose. Tables are given showing that the mean error is approximately 5 per cent. In the second section, the lactic acid concentration of human blood during rest is first investigated. The average value of a series of determinations on four subjects is found to be 27 mg. of lactic acid per 100 c.cm. of blood, the extreme values found being 21 and 31·5 mg. per cent. The difference between the lactic acid figures of fasting subjects and those who have had a breakfast of bread and milk is shown to be negligible. Then follows an investigation of the lactic acid concentration in blood during muscular work, using a cycle-ergometer. In every case muscular exercise produces hyperlactacidæmia, the increase being greater in the first minutes of exercise than later. Large outputs of work (over 1000 kg. meters per minute) bring about a considerable increase of lactic acid concentration in the blood; on resting, this slowly falls off, reaching the normal value again in about half an hour. Mild exercise causes this falling off to be slightly more rapid. The hyperlactacidæma is due to a shortage of oxygen, and the oxygen debt calculated from the lactic acid present is approximately equal to that actually found. The urinary lactic acid after physical exercise may increase to 1 per cent., the excretion in the urine being increased by the administration of alkali.

The author then proceeds to investigate the lactic acid concentration of blood and urine in subjects

Reviews and Notices of Books.

TRAUMA AND COMPENSATION IN OBSTETRIC AND GYNÆCOLOGICAL CASES.

By DOUGLAS MARSHALL LINDSAY, M.D., F.R.F.P. & S. Glasg., Senior Assistant Visiting Surgeon, Royal Samaritan Hospital, Glasgow. London and Edinburgh: William Hodge and Co., Ltd. 1928. Pp. 172. 7s. 6d.

THIS book is a useful contribution to a subject either cursorily dismissed or not considered at all in obstetric and gynæcological treatises. Yet, as the author points out, application for damages is very common among women, and real or fancied injury to a pregnancy offers "a good background for the staging of a case before an impressionable jury." The number of cases quoted from Dr. Lindsay's own experience serves to show both the frequency of claims of this kind and the solid foundation of practical knowledge on which this book is built. The instructions as to methods of examination, the way to record findings, and the precautions to be taken when giving an opinion are excellent.

Concerned, as it is, with a very special side of obstetric and gynæcological practice, this book may not appear to be of general interest, but even a superficial glance reveals many points that have a much wider application than its title suggests. It contains, for example, an excellent review of the diagnosis of pregnancy in which the various symptoms and signs are weighed and the value appraised of those that are of use in estimating the stage that the pregnancy has reached, and in determining the life or death of the fœtus in utero. One sign in the diagnosis of pregnancy, that form of external ballottement known as "dipping" has been overlooked. To many it is the most certain and quickest method of differentiating the pregnant uterus from other cystic swellings at or about the umbilical level and before fœtal parts can be distinctly recognised.

Dr. Lindsay makes a very definite statement that trauma is never a causative factor in the production of a neoplasm; his views on this question are diametrically opposed to those expressed by Dr. Janet Lane-Claypon in regard to injury as an ætiological factor in mammary carcinoma (Ministry of Health Report No. 32). Sarcoma of bone appearing after injury he regards as "having probably been the precursor of the fracture." Whilst refusing to consider a traumatic cause for pelvic growths, simple or malignant, he gives full consideration to the possibility of their being adversely affected by injury, as by the occurrence of torsion, rupture, necrosis, and infection.

The volume has closed a distinct gap in gynæcological literature, and will be found exceedingly helpful to those who have to make frequent appearances in the law courts to give a medical opinion in those compensation cases or actions for damages in which possible pelvic injury to women is in question. The author's experience in obstetrics and gynæcology, and as assistant to the Professor of Medical Jurisprudence in Glasgow, makes his advice of particular value in such cases.

EXPERIMENTAL EMBRYOLOGY.

By THOMAS HUNT MORGAN, Professor of Experimental Embryology in Columbia University. New York: Columbia University Press. 1927. Pp. 766. 37s. 6d.

THE introduction of experimental methods, chemical, physical, and physiological, into embryology is an important development. Although such methods have been applied for over 40 years by a few scattered workers and have yielded fruitful results, these results have so infrequently been brought to the general notice that those not intimately familiar with the work have difficulty in correlating them and in appreciating their full significance. Prof. Morgan's book, which is a complete and critical survey of the important experimental researches, will be welcomed. Moreover, it will appeal to a wider section of scientific workers than did the older embryology books, which described the building up of evidence in a chain of pictures revealed by the microscope. The experimentalists have called into play methods more proper to the chemical and to the physiological laboratories. This change of outlook has revealed new lines of attack on the problems presented by each stage in the complicated process of development. The changes which take place in the process of fertilisation of the egg are vast and complex. Already the amount of fruitful experimental research relating to that incident alone, including the questions of the activity, chemotaxis and agglutination of spermatozoa, the fertilisation, membrane and its functions, selective fertilisation, cross-fertilisation, and polyspermy, exhausts eight chapters, or over 100 pages of the book.

The remaining six hundred odd pages are occupied with the questions involved in the changes in cytoplasm prior to cleavage of the cell, and in the movements of groups of cells following cleavage. Such matters as growth, reflex actions, and trophistic movements of larvæ, sex determination, embryonic grafting, the influence of environment on the development of the embryo, and the source of energy of development, are promised for a future volume. The investigations relating to each section are recorded more or less in their chronological order. The author's conclusions, which are restrained and conservative, are inserted into the text at intervals none too frequent. His obvious reluctance to introduce speculative matter might indeed have been modified to the extent of furnishing short summaries at the end of each section, for an historical account of such complex work must necessarily in places be disjointed, calling for effort on the part of any reader anxious to understand the trend and significance of the progress made. However, since Prof. Morgan provides over 2000 references to works on experimental embryology and sets forth concisely and lucidly a description of practically every important piece of work that has been done on the subject, no one need complain.

To workers in every branch of biology who are seeking for a new line of research this book should provide a mine of inspiring suggestions.

ENDOCRINE DISEASES.

Endokrine Krankheiten. By Prof. Dr. HANS CURSCHMANN, Direktor der medizinischen Universitätsklinik zu Rostock I.M. Dresden and Leipzig: Theodor Steinkopf. 1927. Pp. 151. R.M.8.5.

THE series of monographs to which this volume belongs is designed to give a practical survey of the various domains of medicine. Prof. Curschmann's Endocrine Diseases can claim to have fulfilled this object. Controversial matter has been almost entirely ignored, and where theoretical interpretation is still far from clear the author has contented himself with giving the facts and a short allusion to the difficulties. No condition associated with disease of the endocrine system seems to have been omitted. ENTION OF MENTAL PATIENTS.

l disease may be no more than transient, usly wrong to begin its treatment by eps which will permanently damage a chances in the struggle for existence. agrees, therefore, that certification should resort rather than the normal preliminary are, and the Royal Commission on Lunacy form of machinery designed to give this effect. They recommended that cases stitutional treatment should be differently according to whether the patients were " or "involuntary," and the medical has cordially accepted their suggestion untary boarders" should be admitted into spitals, licensed houses, nursing homes and on the strength of their written application. continues on the question whether such an justifies detention of a patient who objects tment, but for the moment our object is ttention rather to the conditions under can in the first place be regarded as ." The proportion of mental patients ady to accept treatment is none too large, e Commission's plan only these would be from legal intervention. It is true that led reforms would permit of a modified certification in cases where recovery is within six months, for if the prognosis is tient would be treated under a Provisional t Order without actual certification. But an Order to be given the signature of a e would be required, and it is far from ble to argue that it is this intervention l officer, with its attendant publicity, that e social stigma of insanity. Bearing this the Representative Body of the British Association, as we recorded on p. 240 of of August 4th, reached the conclusion that missioners' reforms do not go far enough, e its approval to an alternative plan, the law's intervention would be reserved in which the patient, though capable of definitely refused or resisted institutional t. Under a scheme of this kind the ry" boarders would include all those who categorical objection to being so declared, would undoubtedly increase the number of ho would receive institutional care without een certified. Furthermore, the knowledge tment could be got on these terms would the friends and relatives of a patient to properly looked after at an early stage.

From the medical standpoint, therefore, the Association's proposal has much to recommend it; but there are certain obstacles to its being adopted. In the first place it may be observed that though reform of our lunacy law is inevitable, the prospect of it is by no means immediate. Sir FREDERICK WILLIS, lately chairman of the Board of Control, not long ago described the efforts of the Board to obtain amendment of the Lunacy Acts, and attributed their failure to a public apathy which refuses to be disturbed. The only noticeable symptom of any change in this attitude has been alarm at the restriction of liberty which the law already allows. This manifestation has taken the form of awarding fanciful damages against medical practitioners on the alleged ground of negligence in certification, and its result has been to make administration of the law more difficult, so that we approach a deadlock. What, then, will be the attitude of the public towards the British Medical Association's suggestion that a patient should be admitted to an institution without his consent, merely "on an 'Authorisation for Treatment' given by a relative or friend and supported by a 'recommendation' signed by two medical practitioners"? Will they not regard this as evidence of a desire on the part of medical men to be given powers altogether outside their proper province? Will they not think of it as another and flagrant attempt to strengthen the grip of the profession on mankind? The liberty of the subject is a national ideal, and one which no law reformer is likely or anxious to ignore. Though the law, in varying degrees at various stages of its history, has regarded the lunatic, the married woman and the infant as not fully capable of legal rights, Parliament would hardly dare to-day to decree that any of these classes of persons should be compulsorily detained in the absence of judicial proceedings.

One aspect of this proposal deserves more thought, perhaps, than it has yet received. If mental patients are to be placed in institutions without their express consent, on the decision of a relative or friend, recommended by two doctors, an unavoidable responsibility is bound to fall on the medical men concerned. Civil actions would certainly be brought against them from time to time, and it would not be at all surprising if lay juries were to make the most of these opportunities of registering a natural dislike of iatrarchy, or government by doctors. The profession is at the moment averse from increasing the number of vulnerable areas in its own skin, and is, indeed, anxious to disclaim a good deal of the responsibility placed upon it under the present Lunacy Acts. It is increasingly felt, moreover, that the further protection, which (to quote the Royal Commission) "should be given to medical men in the discharge of their professional duties in relation to insanity," can best be obtained by putting more of the onus of certification upon the representatives of the law rather than by taking it away from these officials. While no practitioner would wish to escape his proper liability to take due care, the British Medical Association's Representative Body has itself approved the principle that "the judicial authority, when it intervenes, shall accept responsibility for the detention of persons of unsound mind." And, oddly enough, this attempt to minimise medical responsibility is more likely to win public approval than the Association's plan for minimising legal intervention; though the former is made purely in the interest of the profession, whilst the latter is designed entirely for the benefit of mental patients.

where impeded oxygen intake might be supposed to lead to hyperlactacidæmia. Examinations of 29 patients with heart disease, five of which were compensated, are quoted. In compensated heart disease the lactic acid concentration of the blood is normal, but it is frequently increased in cardiac insufficiency. In anæmia the lactic acid in the blood is found to be increased in a large proportion of the cases examined. Pneumonia and pulmonary tuberculosis may lead to increased lactic acid concentration in the blood. Fever does not increase the lactic acid content, but in spastic conditions hyperlactacidæmia is observed. In nephritis this is the case only where uræmia is present.

The book would be more readable if the sections had been planned to form a connected story instead of in a form resembling a series of publications in a scientific journal, but it represents a large amount of interesting work. A well-selected bibliography is included at the end of the volume.

DENTAL PROSTHETIC MECHANICS.

By D. M. SHAW, Curator of the Prosthetic Laboratories, Royal Dental Hospital of London. London: Edward Arnold. 1927. Pp. 373. 21*s*.

THIS book has been written for the dental student and for the laboratory mechanic, and the author expresses a diffident hope that it will interest the dentist as well. He rates his book too modestly. This is a most stimulating and original treatise on practical dental prosthesis. Mr. Shaw has had a wide experience as a teacher, and has also been active in research which has attracted attention from dentists and anatomists. He has not attempted to give a formal account of the steps in the construction of a denture, but rather to consider the various aspects of dental prosthesis and to comment on the underlying chemical, physical, and anatomical principles involved. This leads him into a consideration of many difficult problems which demand the close attention of the reader, but he does not neglect to mention practical tips which the laboratory worker will find useful. His views are not always orthodox, and the dentists who have given special study to dental prosthesis may find themselves in conflict with some of them; but they will not find it easy to dispose of his arguments. Among the sections to be singled out for special praise are those on the setting up of artificial teeth, articulators and metal-plate work. The preliminary chapter on the arrangements of the natural teeth is a useful contribution to an aspect of dental anatomy which has not received much attention.

The style in which the book is written is rather involved, and it is sometimes difficult to follow Mr. Shaw's meaning, but the effort is worth making, for the book shows real originality. It is well illustrated and excellently produced.

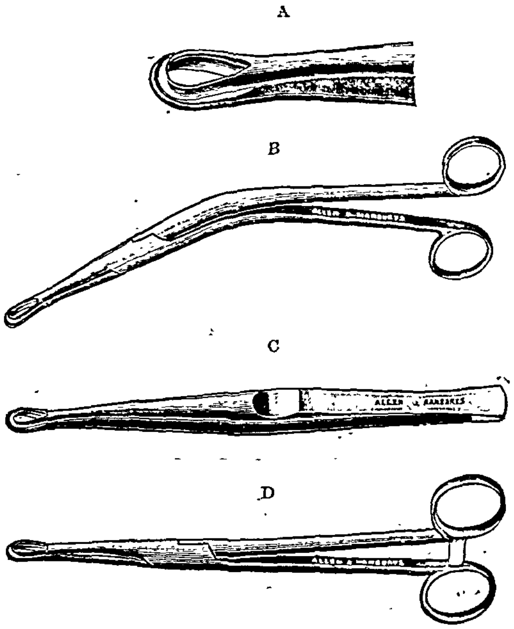
JOURNALS.

MEDICAL WOMEN'S INTERNATIONAL JOURNAL.—The May issue (Vol. I., No. 6) is given up entirely to the proceedings of the open meeting of the Medical Women's International Association held at Bologna from April 11th to 14th last. Summaries are given of all the 34 papers on the two subjects selected for discussion—viz.: (1) medical measures for the protection of children in various countries; and (2) diseases of the eye in relation to general medicine. The abstracts are printed in English or French, the journal being reluctantly restricted to these two languages on financial grounds. It is understood, however, that the Italian association of medical women is bringing out its own report of the proceedings, and the German association publishes its own monthly journal. The papers, given in summary, are well worth careful study, and it is a pleasant surprise to find an example of an international journal which does not contain typographical errors.

New Inventions.

IMPROVED FORCEPS.

SOME years ago when working out an instrument for holding that very friable organ, the tonsil, during dissection, I designed a grip which I believe to be both new and of a fairly wide application in surgery. Its principle is to produce a ruck in the material grasped by its blunt overlapping jaws (A), much in the way of the Army Regulation fastener for webbing straps. It is obvious that a grip of this sort will tear out less easily in flimsy material than one that depends for its hold on piercing or crushing. The original tonsil forceps (B) proved so popular that I have had two other models made—a tissue forceps (C) which is very useful for holding tuberculous glands, cyst walls, and other "washy" tissues, and a bowel forceps (D) which I think will grip intestine more firmly and with less damage than anything else I have ever tried.



The forceps are made by Messrs. Allen and Hanburys, 48, Wigmore-street, W.

Reports and Analytical Records.

EUROSPA.

(S. R. TOOGOOD, 173, KING'S-ROAD, HARROGATE.)

EUROSPA is a cream-coloured powder which claims to possess the curative properties of the salts contained in the natural medicinal waters of Harrogate, Bath, Wiesbaden, and Vichy. On analysis, the following results were obtained:—

Moisture	6·10 per cent.
Matter, insoluble in water ..	9·16 „
Matter, soluble in water ..	84·74 „

The insoluble matter consisted of magnesium phosphate and a little sulphur. The soluble matter comprised sodium sulphate (37 per cent.), magnesium sulphate (16 per cent.), small amounts of potassium salts, tartrates, and citrates, and traces of lithium and chlorides. The sulphur (2·5 per cent.) probably is present as "potassa sulphurata." When dissolved in water the solution was slightly alkaline and had a distinct odour of sulphuretted hydrogen.

TENTION OF MENTAL PATIENTS.

l disease may be no more than transient, ously wrong to begin its treatment by eps which will permanently damage a chances in the struggle for existence. agrees, therefore, that certification should resort rather than the normal preliminary are, and the Royal Commission on Lunacy form of machinery designed to give this effect. They recommended that cases nstitutional treatment should be differently according to whether the patients were y" or "involuntary," and the medical has cordially accepted their suggestion ntary boarders" should be admitted into spitals, licensed houses, nursing homes and on the strength of their written application. continues on the question whether such an justifies detention of a patient who objects tment, but for the moment our object is ttention rather to the conditions under can in the first place be regarded as y." The proportion of mental patients eady to accept treatment is none too large, e Commission's plan only these would be from legal intervention. It is true that led reforms would permit of a modified certification in cases where recovery is within six months, for if the prognosis is tient would be treated under a Provisional t Order without actual certification. But an Order to be given the signature of a e would be required, and it is far from ible to argue that it is this intervention l officer, with its attendant publicity, that e social stigma of insanity. Bearing this the Representative Body of the British Association, as we recorded on p. 240 of of August 4th, reached the conclusion that missioners' reforms do not go far enough, e its approval to an alternative plan, the law's intervention would be reserved in which the patient, though capable of definitely refused or resisted institutional t. Under a scheme of this kind the ry" boarders would include all those who categorical objection to being so declared, would undoubtedly increase the number of ho would receive institutional care without een certified. Furthermore, the knowledge tment could be got on these terms would e the friends and relatives of a patient to properly looked after at an early stage.

From the medical standpoint, therefore, the Association's proposal has much to recommend it; but there are certain obstacles to its being adopted. In the first place it may be observed that though reform of our lunacy law is inevitable, the prospect of it is by no means immediate. Sir FREDERICK WILLIS, lately chairman of the Board of Control, not long ago described the efforts of the Board to obtain amendment of the Lunacy Acts, and attributed their failure to a public apathy which refuses to be disturbed. The only noticeable symptom of any change in this attitude has been alarm at the restriction of liberty which the law already allows. This manifestation has taken the form of awarding fanciful damages against medical practitioners on the alleged ground of negligence in certification, and its result has been to make administration of the law more difficult, so that we approach a deadlock. What, then, will be the attitude of the public towards the British Medical Association's suggestion that a patient should be admitted to an institution without his consent, merely "on an 'Authorisation for Treatment' given by a relative or friend and supported by a 'recommendation' signed by two medical practitioners"? Will they not regard this as evidence of a desire on the part of medical men to be given powers altogether outside their proper province? Will they not think of it as another and flagrant attempt to strengthen the grip of the profession on mankind? The liberty of the subject is a national ideal, and one which no law reformer is likely or anxious to ignore. Though the law, in varying degrees at various stages of its history, has regarded the lunatic, the married woman and the infant as not fully capable of legal rights, Parliament would hardly dare to-day to decree that any of these classes of persons should be compulsorily detained in the absence of judicial proceedings.

One aspect of this proposal deserves more thought, perhaps, than it has yet received. If mental patients are to be placed in institutions without their express consent, on the decision of a relative or friend, recommended by two doctors, an unavoidable responsibility is bound to fall on the medical men concerned. Civil actions would certainly be brought against them from time to time, and it would not be at all surprising if lay juries were to make the most of these opportunities of registering a natural dislike of iatrarchy, or government by doctors. The profession is at the moment averse from increasing the number of vulnerable areas in its own skin, and is, indeed, anxious to disclaim a good deal of the responsibility placed upon it under the present Lunacy Acts. It is increasingly felt, moreover, that the further protection, which (to quote the Royal Commission) "should be given to medical men in the discharge of their professional duties in relation to insanity," can best be obtained by putting more of the onus of certification upon the representatives of the law rather than by taking it away from these officials. While no practitioner would wish to escape his proper liability to take due care, the British Medical Association's Representative Body has itself approved the principle that "the judicial authority, when it intervenes, shall accept responsibility for the detention of persons of unsound mind." And, oddly enough, this attempt to minimise medical responsibility is more likely to win public approval than the Association's plan for minimising legal intervention; though the former is made purely in the interest of the profession, whilst the latter is designed entirely for the benefit of mental patients.

RECENT FOOD INFECTIONS.

LONDON and the home counties have been unpleasantly aware, during the last week or two, of the prevalence of an infectious fever of the enteric group, some 90 cases being under treatment in the M.A.B. hospitals on August 14th. The disease has shown no respect for age or class, and has not been localised to any one area, although certain districts such as Kensington and Epsom have furnished most of the cases. On the whole the symptoms have been mild, the chief being headache and fever. In the average case there has been no vomiting and no diarrhœa, but rather constipation; the majority have shown rose spots in abundance, and a slightly enlarged spleen. Though a few cases have been severe and one death has been reported from Epsom, the outbreak cannot be regarded as really alarming. The organism responsible is *paratyphosus-B*, distributed it is presumed by food; while no particular comestible can as yet be definitely incriminated, cream is under grave suspicion. Since the beginning of the year it has not been permissible to add preservatives to cream and the suggestion has been made in many newspapers that there is some connexion between this prohibition and the present outbreak of infectious fever. A priori this is unlikely, for it has been shown that the maximum addition of boric acid heretofore customary—namely, 0·4 per cent.—has no effect on the growth or vitality of the paratyphoid bacillus, and that five times the quantity is needed to exert any restraint on the organism. It should be borne in mind, also, that in the ordinary course of events paratyphoid organisms in cream originate from the organisms in the raw milk from which the cream was derived. If it were true that they are commonly present in cream, but have hitherto been rendered innocuous by boric acid, then it would be difficult to explain why no milk-borne epidemic of paratyphoid has been recorded in recent years, for no preservatives have been tolerated in milk itself since 1912. This is not to say, of course, that cream, like other foods, may not be accidentally contaminated after separation. Five years ago a big epidemic owed its origin to ice-cream which had been cooled in filthy surroundings.

The paratyphoid outbreak has been confused in the public mind with a group of cases of food-poisoning among the London police force, leading to the death of a constable. But although they were coincident in time the two epidemics were fundamentally different in nature. The usual symptoms of infection with so-called food-poisoning bacilli are vomiting and diarrhœa, the excreta often being blood-stained. There is evidence of intense toxæmia, and the rapid onset, perhaps with prostration, is in marked contrast with the slow and mild development of illness due to paratyphoid-B. Acute enteritis following the ingestion of food used to be described as "ptomaine poisoning," when it was supposed that the symptoms were due to substances produced by the decomposition of proteins, but it is now recognised that the symptoms are due to the multiplication of organisms of the food-poisoning group within the intestine, and in severe cases within the blood stream. The food-poisoning bacilli occurring in preserved meats such as sausages, pies, and the like, may have come from an infected cow or pig, or from subsequent contamination of healthy meat. The meat or food may not present any unusual features either to the taste or smell, although there can often be isolated from it an organism identical with that obtained from the sick individual.

All these infecting agents, paratyphoid bacilli and the food-poisoning organisms alike, however different may be their results clinically and epidemiologically, are closely related and belong to the salmonella group, which comprises a number of organisms which cannot be distinguished from one another under the microscope. Their biochemical characters are also similar and separation of members by fermentation tests is not possible. They differ in their serological relations, but even here the group relationship between certain types may be so close as to demand complicated methods, such as agglutinin-absorption tests for their identification. Of the three types of paratyphoid bacilli, "A" does not occur in this country, "C" is met with occasionally, while "B" infections are common, and in recent years have assumed a greater relative importance than typhoid fever. The food-poisoning bacilli comprise: The *B. enteritidis* of Gaertner, which was found in the recent police cases, and the *B. aertrycke*, the commonest food-poisoner in this country, of which at least four types have been described. All these agree in the essential characteristics that: (1) they multiply in food with great rapidity, especially during warm weather; (2) during their growth in food they produce no physical changes visible to the naked eye; and (3) the toxins produced are highly resistant to heat.

◆

EXPERIMENTAL DENTAL CLINICS.

IT is generally agreed that in schools and industrial enterprises the dental clinic has proved its worth, and the Minister of Health has taken power, under the Amending Act, to set up a number of experimental clinics for dental treatment under the National Health Insurance scheme. This experiment has a significance both for medical and dental practitioners, since their interests under the Acts are closely related.

The amount of dental additional benefit distributed has steadily increased during two valuation periods, but it seems certain that its present partial and conditional application will extend over the period of the third valuation which is approaching. Notwithstanding the fact that nearly £2,000,000 per annum is available for the purpose, the present scheme is far from covering the entire field. All insured persons are not yet entitled to the benefit; those who are eligible are called upon to pay a large proportion of the cost of treatment, and none can claim it during those important years of adolescence from 16 to 21 years of age. If we ignore these serious deficiencies, it must be admitted that the scheme has been largely successful. A satisfactory system of dental service has been evolved and maintained on a voluntary basis, and this is especially noteworthy because in the original Act there was little provision for regulating the administration of additional benefits, and consequently the conditions of service—including the delicate matter of remuneration—had to be negotiated by conference between representatives of the dental profession and of approved societies in an atmosphere of imperfect mutual confidence. As it now stands the scheme is applicable to England, Scotland, and Wales. It is managed by a Dental Benefit Joint Committee consisting of equal numbers of dentists and approved society representatives, with subsidiary committees for interpretation, investigation of disputes and for appeals; there is a Regional Dental Officer service, and there is even a disciplinary tribunal consisting of a barrister and two dental assessors. No panel in the medical sense is at present in existence, but there has been no difficulty in securing the necessary service, the insured person being permitted to consult any dentist who is prepared to give the treatment on the agreed conditions.[1] A few approved societies have caused trouble by refusing to take part in the scheme, and their efforts to secure treatment for their members at fees lower than those of the agreed scale have had a disturbing effect. There have also been the inevitable clashes caused by lay officials who considered that control of the funds gave them the right to interfere with the professional discretion of the dentists. The latter, on their part, have occasionally shown an unfortunate sensitiveness as well as a somewhat irritating tendency to ignore agreed conditions. But, on the whole, the method of giving treatment through the agency of private dental practitioners seems to have justified itself, and this method is likely to remain the chief means for administering this important benefit. The demand for dental clinics has thus no warrant in any failure of the present system.

By no means new, the suggestion that clinics should be established was familiar to those who had to deal with the approved societies during the first valuation period, when it was put forward by certain officials with the frank intention of getting more effective control over the dentists they wished to employ. The idea was to place one or more dentists in operating rooms in proximity to the offices of the approved society, which would itself settle conditions of service, supervision, and remuneration; in short, it was desired to apply to dental insurance practice the methods of the pre-insurance "medical club" system. When later, on the institution of the present Dental Benefit Joint Committee, the Minister of Health asked the Committee to inquire into "the possibility of the institution of clinics for dental treatment in particular areas and the desirability of encouraging steps to this end on the part of the dental profession," the earlier attitude towards the clinic question was largely abandoned, and stress was laid on the necessity for obtaining for insured persons a uniform standard of dental treatment in return for the payment of a uniform scale of fees. Attention was drawn to the advantages of large establishments, fitted with equipment and apparatus for special forms of diagnosis and treatment, and having facilities for team-work such as were not generally available in private surgeries; the clinic, it was expected, would also act as a propagandist centre for dental hygiene. The setting-up of such institutions is, however, only possible in populous areas, and preliminary inquiries on initial cost and running expenses do not encourage the idea that the present cost of treatment would be materially reduced. Nevertheless it is clear that clinics might play a useful though limited part in the future treatment of insured persons, and the assurances about their control, given by the Minister, and the actual embodiment in the Amending Act of the principle of free choice of dentist, have gone a long way towards reconciling the dental profession to an experiment of which it had been suspicious, as was hardly surprising. It must not be forgotten that the present position of the profession, of whose members only about one-half possess qualifications obtained after recognised courses of study and examination, necessarily results in a certain inequality of service available to those who get their dental treatment under the National Health Insurance scheme. The experimental clinics will test the possibility of providing a high standard of dental treatment in circumstances under which, otherwise, it may not be always available. If insured persons, of their own choice, attend them in sufficient numbers, and if the treatment given in the clinics is maintained at the level of excellence which is contemplated, their establishment will be justified from the standpoint of public health, and, in any case, the experiment, with all its results made freely available to interested parties, cannot fail to be useful.

NON-PULMONARY TUBERCULOSIS.

SEVERAL important issues are raised in the papers in our present issue, by Mr. J. T. MORRISON on human and bovine types of tuberculosis in man, and by Dr. C. O. STALLYBRASS on the sources of infection. Both deal with non-pulmonary tuberculosis, a type of the disease which is all too often neglected in discussions on infectivity. Mr. MORRISON's inquiry concerns the effects of inoculating guinea-pigs with material from tuberculous lesions, with a view to correlating clinical and bacteriological findings, and in almost one-third of the cases he found that this test was negative. For various reasons it is considered that failure to produce tuberculosis in the experimental animal was not due to the paucity of organisms, nor to a high state of immunity as reflected in the clinical course of the patient's illness; but rather to local conditions, such as the presence of fibrosis in the lesion from which the material was obtained. This view was supported by the long history of some of the cases, and seems by no means unreasonable, since it is well recognised that fibrotic and calcified foci are least likely to yield tubercle bacilli on animal inoculation. It would be a valuable aid to the elucidation of this point if material were inoculated from different portions of the lesions and at different times in the history of the same patient—i.e., in the early active stages and again in the later quiescent stages. An investigation into the human and bovine origin of these cases showed that failure to induce tuberculosis in the guinea-pig was as common with the one type of bacillus as with the other, so that the question of the relative toxicity of the two types of bacillus for the guinea-pig was apparently not considered to require investigation.

Mr. MORRISON raises a number of other questions on the regional distribution and clinical condition of the bovine and human groups. Tuberculous glands of the neck were found to be of bovine origin in 75 per cent. of cases, whilst the bovine bacillus was only responsible for 28 per cent. of the bone cases. These figures emphasise the need for a much more careful geographical survey of both bovine and human tuberculosis. Why, for instance, should Edinburgh have a high percentage of bovine lesions? Again, why should Jarrow, as shown by recent statistics, have a markedly higher total tuberculous incidence than Tyneside in general? Average figures for the country as a whole are of course of the utmost value, but there is some danger in assuming that they are necessarily typical of local conditions, and in so doing a remedial local factor may be overlooked. Statistics, moreover, do not remain of permanent value. Are we not in danger of making false deductions, for instance, from figures of positive findings of tubercle bacilli recorded in milk and butter in periods before the war? Every generation ought to make its own investigation afresh.

---

[1] These are set out, together with full information on the working of the scheme, in a Dental Benefit Handbook compiled by the Dental Benefit Joint Committee and obtainable from H.M. Stationery Office at a nominal cost.

There is need, too, in the case of bovine tuberculosis for a regional survey of dairies and milk supplies, and we believe that such a survey might show that the bovine bacillus is not so widely distributed as was at one time believed. On the clinical side Mr. MORRISON's inquiry shows that the history of onset of the disease was earlier in the bovine than in the human bacillus series. This again is important. It is likely that younger children, drinking more milk, are more prone to bovine infection than older children, but we have been led to believe of late that the human type of infection is also contracted during early years. Mr. MORRISON's figures do not quite bear this out as far as non-pulmonary tuberculosis is concerned. A study of family history and an inquiry into possible portals of entry were not very successful as a guide to bovine versus human infection, but the results of treatment in the two types of case were remarkable. In all the bovine cases traced the patients were in good health, whereas more than 18 per cent. of the human cases had proved fatal within three years.

Dr. STALLYBRASS, also dealing with Liverpool cases, gives the results of inquiries into 4469 non-pulmonary cases of tuberculosis. From his figures it appears that tuberculosis of bones and joints is relatively common in patients giving no history of exposure to a human source of infection, whereas meningeal and abdominal tuberculosis—and to a less extent tuberculosis of peripheral glands—was in excess in those giving such a history. These deductions have to be somewhat modified for children, but, broadly speaking, Dr. STALLYBRASS thinks there is a direct contradiction between the figures as analysed for exposure or non-exposure to a possible source of human infection, and between the well-known results of bacteriological investigation. We are not so sure that exposure to human infection can be taken as a crucial test of invasion by the human bacillus. The tubercle bacillus is a slow starter, and the race is not always for the swift; the history of human infection may well be overlooked. The significance of certain details of personal history often escapes even the most skilled questioner, whilst the primary case in the household may remain dormant, from the physician's point of view, for many years. Conversely, bovine infection is rarely in evidence. On the whole, therefore, we are inclined to place most reliance on the bacteriological findings, but Mr. MORRISON and Dr. STALLYBRASS have raised many interesting questions, and are to be congratulated on exploring the field of non-pulmonary tuberculosis as against the pulmonary type of the disease. Far too little original work has been done of late years in this field, and it may well be that investigation of this kind will open up new views on the prevention of tuberculosis, particularly as regards contacts, disinfection, the milk problem, and the like. A large proportion of our national health budget is devoted to tuberculosis, and the elucidation of these questions may result in saving of money.

DONATIONS AND BEQUESTS.—The late Viscount Hambleden, among other bequests, left £5000 to King's College Hospital.—Mr. E. F. Goulburn, of Southport, left, subject to his wife's interest, £2000 to the Victoria University of Manchester to be applied for research purposes in connexion with megrim as affecting humanity, and £500 to Manchester and Salford Playing Fields Association.—Mr. Evan Lewis, Swansea, left £1000 to the Swansea General Hospital, to endow a bed.—Mr. W. R. Morris, head of the firm of Motor-car manufacturers at Oxford, and President of the Infirmary, has promised a gift of £38,000 for the extension of the Radcliffe Infirmary, Oxford. The gift will be used for the building of a new maternity home.—Mr. Tom Jackson, of Heaton, Bolton, left £1000 each to General Fund of the Victoria University, Manchester, the Bolton District Nursing Association, Dr. Barnardo's Homes, and the London Missionary Society.—Mr. Ernest George Wragg, of Ranmoor, Sheffield, left £1000 to the Jessop Hospital for Women to endow a bed in memory of his wife, £1000 to the Rotherham Hospital for the endowment of a bed in memory of his parents, and £500 to the Sheffield Children's Hospital for the endowment of the "William" cot.

HEALTH HAZARDS IN INDUSTRY.

RECOGNITION is given in the United States to the social importance of the Registrar-General's Decennial Supplement dealing with Occupational Mortality,[1] by the devotion of a whole Public Health Report[2] to a summary of its facts and deductions. We are thus afforded an opportunity of knowing how others regard the data and their presentation. America possesses no comparable material—nor, indeed, has any other country; and turns with avidity to our occupational mortality-rates as being exceptionally suggestive. The social distribution of mortality, portraying the influence of financial standing upon disease, has little appeal to the United States, except as introducing an element of uncertainty into occupational environment. Possibly a country so prosperous as the United States finds even its lowest social class hardly at all hit by the dysgenic influence of penury. The association is noted of such digestive diseases as diabetes and diseases of the liver with financial capacity for over-indulgence in dietetic indiscretions. Then attention is devoted to specific occupational comparisons in the search for clues to hidden industrial hazards. Here the significance of dust as a cause of tuberculosis, especially of silica dust, is stressed. The evidence adduced receives synchronous support from research just published by the Metropolitan Life Insurance Company of New York,[3] wherein the proportion of deaths from tuberculosis for certain occupations with a silica dust hazard is shown to exceed the average for all males: for metalliferous miners by 83 per cent., for pottery workers by 77 per cent., and for stone cutters by 44 per cent. A point is made that where this specific hazard exists there is a tendency for the phthisis mortality to rise steadily with age, and so present a form of curve unique for this cause of death. The facts are carefully examined as to mortality due to all other respiratory diseases. Occupations with high rates are placed in five groups: one is exposed to dusts; a second to high temperatures—e.g., furnacemen; a third to inclement weather—e.g., dock labourers; a fourth contains rejects from other trades—e.g., costermongers; and a fifth includes the alcoholics. In this connexion the incomparability of death-rates in the two countries ascribed to chronic bronchitis receives attention. In the United States certification of chronic bronchitis is discouraged, so that in New York medical certificates stating chronic bronchitis as a cause of death are sent back for revision. Hence bronchitis death-rates are usually about one-fourth those in England and Wales; while cardiac death-rates are proportionately swollen, since English bronchitis becomes American myocarditis. Direct occupational risks, however, affect a relatively small group of the working population, while the conditions of life implied by various occupations exert subtle and pervasive influences on mortality in many indirect ways. The British data are recognised as providing evidence of the existence of such influences.

INFLUENCE OF POSTURE ON RENAL FUNCTION

THE relation of posture to albuminuria in susceptible subjects has long been recognised, and at one time came in for a good deal of investigation, but evidence on the effect of postural changes upon the renal function is still scanty. Exactly a quarter of a century ago Linnoisier and Lemoine, using the methods then in vogue, adduced good evidence of an increase in the activity of the kidney when the body was recumbent, but in spite of the development of new methods of investigating the renal function their results seem to have gone unconfirmed. N. Cordero and M. H. Friedman,[1] working in the Physiological Laboratories of the University of Chicago, have now reinvestigated the question, using means of the phenolsulphonephthalein test of Rowntree and Geraghty. They employed two normal subjects for their experiments, which extended over seven months, and their results show clearly a diminution of excretion of the dye in the upright and an increase in the recumbent position. They were further able to demonstrate corresponding alterations in the excretion of water. A large body of evidence goes to show that the excretion of phenolsulphonephthalein runs parallel to that of nitrogenous bodies in the urine; Linnoisier and Lemoine demonstrated a decrease in chloride excretion in the upright position and an increase in the recumbent. In view of all these facts the assumption seems fully justified that the recumbent position favours, while the upright inhibits, renal activity. The why and wherefore of this phenomenon remains as obscure as it was when Linnoisier and Lemoine[2] originally produced the theory of torsion of the renal pedicle resulting from erect posture. The American investigators suggest that increased urinary excretion in the recumbent position may be due to increase of the capillary bed, brought about by vascular dilatation. Such a dilatation may depend not only on the recumbency, but also on the general toning-down of nervous activity, such as precedes sleep. In support of this they adduce the fact that in one of their subjects, who was of a nervous and excitable disposition, the influence of change of posture was less than in the other whose nature was more phlegmatic.

THE BROAD TAPEWORM IN NORTH AMERICA.

It was predicted over 30 years ago that *Diphyllobothrium latum* would become endemic in the upper peninsula of Michigan, seeing that its population contained immigrants who retained their Baltic habit of eating uncooked fish, fresh, dried, smoked, or cured. The prediction has proved correct, and T. Vergeer[3] has been investigating the steps by which this established infection is being maintained. Pike are almost solely implicated as the second intermediate host, that directly concerned in infecting man. They are in the main migratory, passing from the Great Lakes into the rivers to spawn, and in this way reaching Portage Lake in the Michigan Peninsula, the spot where infection is greatest. One infected fish has been caught in Lake Superior, 20 miles from the mouth of the Portage Canal, a distance which marks the limit of the area investigated, so far as Lake Superior is concerned. The local crustacean intermediary has not been determined. That the matter may come to have a more than local interest is suggested by the statement that 7,000,000 pounds of pike belonging to the species which are locally infected were imported into the United States from Canada in 1924, the last year for which figures are available, mostly fresh and unfrozen. It is concluded that it is necessary that these imported fish should be thoroughly examined for the plerocercoids of *D. latum*. Knowledge of the extent, if any, to which they are infected [illegible] valuable, but if a complete food inspection [illegible] this would probably be incompatible with [illegible] tinuance of the trade. Nor does there [illegible] justification for its institution in [illegible] stances, seeing that the human infestation [illegible] associated with peculiar habits [illegible] grants of certain nationalities, that [illegible] limited to the area where these habits exist, and that within that area, it is, in the experience of those in local medical practice, less common than it was 20 years ago. It is significant that all the pike, some 30, examined from Lakes Erie and Douglas, were free from plerocercoids of this cestode.

RACIAL VARIATION IN THE SIZE OF RED BLOOD CELLS.

It has generally been accepted that on the average the red cells of all the races of mankind are of the same size, but actual evidence of this has been wanting. Credit is therefore due to Dr. N. G. Winschnewsky[1] for adducing facts in support of this view. He has examined the red cells of 195 people of various races, all of whom had been domiciled for some months in Moscow, and he has found that the average size of the red cells in members of all the races tested falls within the accepted limits of normality. The extreme measurements of the diameter in the individuals examined were 6·64 µ and 7·83 µ, whilst for the different racial groups they were 7·14 µ and 7·34 µ. So far as it goes, this suggests that there is no appreciable difference between the dimensions of the red cells in individuals of different races living under the same conditions.

ACID DRINKS AND ENAMELLED VESSELS.

A FULL account of an interesting but rather alarming outbreak of sickness, which received some notice in the daily press, is given by Dr. J. A. Charles, assistant medical officer of health for Newcastle-upon-Tyne, in the current *Medical Officer*. Fortunately the investigation which followed the outbreak left no grounds of doubt as to the cause or as to the means of avoiding the possibility of similar occurrences.

A firm employing about 500 people were desirous, during the recent hot weather, of adding to the comfort of their employees by providing iced lemonade for their consumption. The "lemonade," like much of the drink provided under that name, was free from the characteristic acid of the lemon and its allies, citric acid; its place being taken by the usual substitute, tartaric acid. It is to the credit of the makers of the powder used that they called it "fruit crystals," and did not use any word suggesting that it was derived from lemons. The report of Dr. J. T. Dunn, who was called in to make an analytical investigation, showed that this was a perfectly harmless preparation, although a [illegible] hospital, made when the first cases [illegible] to the sufferers being treated [illegible] An investigation of the [illegible] outbreak, which was [illegible] recovery of all the [illegible] that the crystals [illegible] overnight in [illegible] for the [illegible] in the crystals [illegible] may be [illegible] case. HEALTH HAZARDS IN INDUSTRY.

Recognition is given in the United States to the social importance of the Registrar-General's Decennial Supplement dealing with Occupational Mortality,[1] by the devotion of a whole Public Health Report[2] to a summary of its facts and deductions. We are thus afforded an opportunity of knowing how others regard the data and their presentation. America possesses no comparable material—nor, indeed, has any other country; and turns with avidity to our occupational mortality-rates as being exceptionally suggestive. The social distribution of mortality, portraying the influence of financial standing upon disease, has little appeal to the United States, except as introducing an element of uncertainty into occupational environment. Possibly a country so prosperous as the United States finds even its lowest social class hardly at all hit by the dysgenic influence of penury. The association is noted of such digestive diseases as diabetes and diseases of the liver with financial capacity for over-indulgence in dietetic indiscretions. Then attention is devoted to specific occupational comparisons in the search for clues to hidden industrial hazards. Here the significance of dust as a cause of tuberculosis, especially of silica dust, is stressed. The evidence adduced receives synchronous support from research just published by the Metropolitan Life Insurance Company of New York,[3] wherein the proportion of deaths from tuberculosis for certain occupations with a silica dust hazard is shown to exceed the average for all males: for metalliferous miners by 83 per cent., for pottery workers by 77 per cent., and for stone cutters by 44 per cent. A point is made that where this specific hazard exists there is a tendency for the phthisis mortality to rise steadily with age, and so present a form of curve unique for this cause of death. The facts are carefully examined as to mortality due to all other respiratory diseases. Occupations with high rates are placed in five groups: one is exposed to dusts; a second to high temperatures—e.g., furnacemen; a third to inclement weather—e.g., dock labourers; a fourth contains rejects from other trades—e.g., costermongers; and a fifth includes the alcoholics. In this connexion the incomparability of death-rates in the two countries ascribed to chronic bronchitis receives attention. In the United States certification of chronic bronchitis is discouraged, so that in New York medical certificates stating chronic bronchitis as a cause of death are sent back for revision. Hence bronchitis *death-rates* are usually about one-fourth those in England and Wales; while cardiac death-rates are proportionately swollen, since English bronchitis becomes American myocarditis. Direct occupational risks, however, affect a relatively small group of the working population, while the conditions of life implied by various occupations exert subtle and pervasive influences on mortality in many indirect ways. The British data are recognised as providing evidence of the existence of such influences.

INFLUENCE OF POSTURE ON RENAL FUNCTION

The relation of posture to *albuminuria* in susceptible subjects has long been recognised, and at one time came in for a good deal of investigation, but evidence on the effect of postural changes upon the renal function is still scanty. Exactly a quarter of a no evidence to show that during his life he had any active connexion with the healing art, but numerous cures were reputed to have been wrought at his shrine after and before his canonisation. He was elected bishop in 1275, succeeding Peter of Savoy (Aquablanca). He had served as Chancellor of the University of Oxford, and as Chancellor of England, under Simon de Montfort. He was stern in his resistance of encroachments on his liberties, upholding his rights in Malvern Chase against Gilbert de Clare, the Red Earl of Gloucester; disputing with Llewellyn of Wales and with Lord Clifford, the latter for cattle lifting. Lord Clifford performed penance and underwent a birching in the cathedral. The bishop's most severe wrangle was with his metropolitan, John de Peckham, over a question of testamentary jurisdiction. Excommunicated by the Archbishop, he went to Rome and secured from Pope Martin IV. a decree in his favour. On his way back he died, as stated above, and was buried in Florence. His bones were separated from the flesh by boiling and brought to Hereford and placed in the cathedral. His old enemy, the Red Earl, attended the ceremony, and at his approach, the episcopal bones were seen to bleed! Forty years later he was canonised. An enormous number of miracles resulted. More than 66 dead persons were restored to life. His shrine even acquired a sort of veterinary reputation, and Edward I. sent sick falcons to be cured at his tomb. The six lawyers, it will be seen, were asked to dismiss from their minds an extraordinary amount of influential matter before giving their verdict.

HEALTH TALKS.

In the Public Health Section of the British Medical Association's Cardiff meeting Dr. W. W. Jameson dealt with the important and difficult subject of health education, particularly welcoming the use of broadcasting as a means to that end. He commended the suggestion recently made in *Public Health* (May, 1928) that the present method of broadcasting once a month a "health talk" lasting 15 minutes is unlikely to serve the cause of education so well as more frequent four-minute broadcasts on matters of special health interest at the particular moment. He also spoke of an agreement which had been reached with the General Medical Council in regard to the publication of health articles in the daily press, in which connexion a leading newspaper reported him as follows:—

> "It was now accepted that such articles should be submitted to the Chief Medical Officer of the Ministry of Health for his approval and that approval would be forthcoming provided the article was (*a*) for the public benefit, and (*b*) free from the taint of personal professional advertisement. Articles approved by the chief Medical Officer might be signed by the author and might then be distributed through one of the press associations."

These statements may easily be interpreted as an official decision on the vexed question of signed contributions by medical men to the public press, but the facts do not justify such a reading. For some time past the British Broadcasting Corporation has submitted to Sir George Newman, the Chief Medical Officer of the Ministry of Health, such talks on health as they were proposing to broadcast, with a view to assuring himself that the matter to be broadcasted was for the public benefit and free from the taint of personal professional advertising. It seems that the Central Council for Health Education, a recent development of the Society of Medical Officers of Health, proposed to distribute through the press associations a regular series of articles dealing with health subjects, and asked Sir George Newman for his advice whether the publication of such signed articles would be regarded as unobjectionable by the General Medical Council if the authors were (*a*) senior whole-time medical officers of the public health service who in the ordinary course were not likely to apply for promotion to other appointments; or (*b*) retired medical officers no longer seeking professional employment. The Registrar of the General Medical Council, when consulted, thought it desirable that the same principles should apply to this special series of signed articles as to the special wireless talks, and Sir George Newman expressed his willingness to exercise the same censorship over the publication of articles of this kind as he has done in regard to broadcasting. This is, we understand, the position which has been reached at the moment.

MENTAL DISORDERS IN SCOTLAND.

THE record of last year's care of the mentally afflicted and deficient of Scotland[1] contains no mention of novel departures or striking events, but proves that the foundations of lunacy administration are being strengthened and that healthy ideas are gaining ground. The total number of persons under the Scottish Board of Control at the beginning of this year was 18,702, an increase over last year of 122; this increase is all in the pauper class of patients, the number of private patients having slightly decreased. The number of admissions to asylums was 3168, which is 133 more than in the previous year, but 458 less than the average for the previous quinquennium; 703 voluntary patients were admitted, and 815 were resident on Jan. 1st last. This figure shows a remarkable increase, the average for the ten years 1918–27 being only 409. The average recovery-rate on admissions in all institutions, with the exception of lunatic wards of poor-houses, was about 34 per cent (no general rate is given in the report), and the average death-rate was 8·5 per cent. Most of the deaths were due to diseases of the circulation and brain, and there were only seven suicides. The number of mental defectives on the register was 2915, the admissions being slightly less than in the previous year. In discussing the life of defectives in private dwellings one of the commissioners points out once more that strangers look after them better than their own relatives. This fact is well known to all connected with the care of the mentally afflicted, but its explanation is not at first sight obvious. A patient living with strangers may be removed, and guardians will make strenuous efforts to avoid the stigma which they consider this will entail. Parents, from whom the patient cannot easily be removed, are apt to regard themselves as infallible. Many of these parents, moreover, possess a low intelligence and a rudimentary idea of cleanliness. When aliment is stopped because the family's circumstances have improved or the defective has obtained employment, patients and guardians alike are generally anxious to be free from official supervision. These, however, are the cases in which supervision is most necessary, as the labour of defectives is liable to be exploited.

The Board refer to the success of the observation wards which several parish councils have established and which are conducted on hospital lines. Of 1240 patients who passed through those at Stobhill and Duke-street in one year, 788 returned to their homes without the necessity for certification. The Board are anxious to extend the scheme. As they remark, the Royal Commission of 1927 recommended that the functions of the Board of Control and the General Board should be extended to include all matters relating to mental health. The annual lunacy grant, which amounts to £115,000, is given to improve the care of the mentally afflicted, and this object, in the opinion both of the Scottish General Board and of all who are concerned with the problem, would be better accomplished if, instead of remaining as it is—a grant in aid of certified lunatics—it were given to the Board to use at their discretion for the good of all mentally affected persons other than defectives. It could then be applied to the source of the evil instead of to its full flood, and would be many times more effective.

[1] Fourteenth Report of the General Board of Control for Scotland, for the year 1927. H.M. Stationery Office. 2s.

is usually so adjusted that the ordinary acid solutions likely to be used in culinary operations only remove inappreciable amounts of antimony in cases where that element is a constituent of the glaze. Antimony was also found in the "lemonade" taken from the pails. Owing to an oversight the liquid from the bath, which it was found was not enamelled with a fritted glaze, but had been painted with zinc white in linseed oil, was not examined, and it is not certain that any of the liquid in this was consumed, although at first there was an impression that those who drank only from this supply were not attacked by sickness. The lemonade from the pails contained 0·013 per cent. of metallic antimony. This, as Dr. Dunn points out, would represent in an ordinary 10 oz. tumbler gr. 0·57 of antimony, or gr. 1·52 of tartar emetic, whilst the emetic dose given in the British Pharmacopœia is gr. 0·5 to 1·0, so that drinking so little as one-third of a tumbler might be expected to cause sickness. No other heavy metals, such as arsenic or lead, were found in the drink, and the circumstances, including the symptoms observed, were all consistent with simple antimony poisoning.

It is unfortunate that so kind and thoughtful an action on the part of the firm concerned should have led to so much pain and inconvenience, but the tale serves to point some morals. Æsthetic and, perhaps, even common-sense considerations seem to suggest hesitation in adapting utensils designed for one purpose to another. The German makers of slop-pails, in glazing their interiors with a rather low-grade antimonial enamel, could hardly have foreseen that in the pioneer country of sanitary science they would be used as containers for beverages. Possibly, having regard to the adaptable character of the Briton, it might be desirable for such vessels, when sold, to bear a label: "not to be used for food or drink." Occurrences of this kind should receive the widest publicity; in fact, there should be some means whereby brief warnings could be compulsorily published in all newspapers. Further, some international standard for food containers might well be considered, as apart from acute visitations of the kind described, it is surely undesirable that the human body should become a receptacle for traces of antimony, tin, lead, arsenic, and other heavy metals. Last week 30 out of 60 of a party of boy scouts and girl guides were suddenly taken ill after having been regaled with cakes and lemonade, and were unable to return to camp until next morning. It is legitimate to wonder whether this outbreak was due to the same cause as the Newcastle one.

THROMBOSIS OF THE SPLENIC VEIN.

THE diagnosis of splenic anæmia is often made in cases which conform only vaguely to what many authorities regard as at best a vague disorder. From the mixed collection of cases grouped together under this name certain examples of thrombosis of the splenic vein have been separated off, principally by Wallgren, whose original paper has already been noticed in our columns.[1] At the discussion on chronic enlargements of the spleen in children, at the British Medical Association's meeting at Cardiff, Dr. Robert Hutchison referred to the occurrence of this condition in children, and described a case of his own; while in a recent article[2] G. Westkott makes a further contribution to the subject. The essential features of these cases of thrombosis of the splenic vein are the occurrence of severe hæmatemesis in association with enlargement of the spleen—which enlargement is less during and immediately after the hæmorrhage—and the absence of any evidence of cirrhosis of the liver or other cause for the symptoms. Westkott had under his care a girl of ten who was admitted with a profound anæmia, due, he believes, to severe infection with the intestinal parasite, *Trichocephalus dispar*. There was a history of hæmatemesis before admission, and a severe repetition of this followed a blood transfusion while she was in hospital. Elaborate investigations were carried out which excluded other causes of splenic enlargement: the blood count showed a severe secondary anæmia with very slow gradual improvement, unlike that following a serious hæmorrhage. In Westkott's paper the part played by the parasitic infection is discussed at some length, and the relation between this and the thrombosis of the splenic vein which was diagnosed is also considered. Operation was not performed, so that confirmation of the diagnosis was not possible. It is believed that thrombosis in these cases is probably the result of some infection, although the possibility of its connexion with the severe loss of blood by the bowel due to the worm infection has also to be remembered. It may be that the primary fault in these cases of splenic anæmia is a thrombosed splenic vein, and the splenomegaly which follows this may be responsible for the anæmia and also for the character of the white cell count, with leucopenia, so frequently found. Westkott does not come to any definite conclusions except to confirm the idea advanced by Wallgren, that splenic vein thrombosis is a clinical entity. The case he describes opens up further possibilities as to the ætiology of the condition.

THERAPEUTIC MIRACLES AT HEREFORD.

IN his History of Hereford Cathedral the late Canon Bannister states that, as a general rule, the miracles recorded in the "Lives" of mediaeval saints are vaguely described and poorly attested. But of those wrought at the tomb of St. Thomas de Cantilupe it seems that there exists an official account, drawn up by six lawyers after investigations made by papal commissioners. Two of these—Ralph Baldock, Bishop of London, and the Bishop of Mende—came to Hereford at the end of August, 1307, and stayed till Nov. 16th, *omni die ex industria intuentes ecclesiam.* Pope John XXII., in the Bull of canonisation, declares that 17 miracles were thoroughly investigated and found to be *fidelibus probata testimoniis.* A large *proportion of these 17 miracles* were cures of cases of palsy, but three deal with cases of blindness, and Bannister says that the evidence for them is probably better attested than the evidence for marvellous cures at any other shrine. The fifteenth of the series concerns Agnes de la Brok, of the parish of St. Martin's, Hereford, cured of blindness on the Friday after the octave of Easter, 1287. One witness affirmed that Agnes was well-to-do, so that there was no apparent reason for her wishing to make money out of her infirmity. Several witnesses deposed that she had not in her blinded eyes, *vulnera, apostema, tumorem, maculam, vel aegritudionem vel aliquam apparentem laesionem.* This seems to have been a case of hysterical blindness. Last in the series of cures come two small boys, brothers, aged 4 and 5 years respectively, healed of their blindness, also in 1287. *Mali humores effluebant ex oculis, et aliquando claudebantur palpebrae dictorum oculorum: tunc ipsi oculi inflabantur, et putredine congregata in eis denuo palpebrae aperiebantur.* Obviously these were cases of simple catarrhal ophthalmia. Presumably Agnes and the children had died or passed out of ken during the 20 years intervening between their miraculous cures and the official inquiry, or their first-hand testimony would have been obtained.

Judged by modern standards one feels that the six lawyers who investigated these cures must have been very easily satisfied, but the inquiry was held upon the findings of papal commissioners, and when St. Thomas de Cantilupe, recently dead, was at the crest of his fame as a miracle worker. For this saint, one of the most celebrated of the Bishops of Hereford, died on August 25th, 1282, at Civita Vecchia. He is reputed to have been of a saintly disposition, and was certainly steadfast and unyielding in upholding the rights of the See. There is, so far as we are aware, an anatomical basis, and he considered that we could attribute little or no importance to the factor of autotoxæmia. There was present an instability of affective mind resulting from heredity and possibly connected with vasomotor variations.

---

[1] THE LANCET, 1927, ii., 823.
[2] Jahrb. f. Kinderheilkunde, June, 1928.

Autotoxæmia was of considerable importance in true or idiopathic epilepsy as distinct from symptomatic epilepsy. In many cases it was possible to demonstrate anatomical changes. For instance, Weiner had described gliosis of the cerebral cortex, Chaslin alterations in the cornu ammonis, Speilmeyer leptomeningitis. Endocrine influences might also play a part, the suprarenal, thymus, corpus luteum, and possibly the pineal gland, all tending to increase the instability of the cerebrum and to predispose to convulsions, while the parathyroids, gonads, pituitary, and possibly the pancreas, decreased this tendency. Hepatic influence in mental disorders remained uncertain. Kirschbaum had described degeneration in the corpus striatum and pallidum in the cerebral cortex in association with acute yellow atrophy of the liver. Prof. Weygandt attached no great importance to bodily fatigue and hunger, in the production of mental disease, but insomnia might have a definite influence.

In summarising, Prof. Weygandt stated that in many cases of mental disorder considerably biological and biochemical changes occurred which could be explained by autotoxæmia. The facts discussed had also been applied to treatment. Preparations of thyroid gland were successful in the treatment of myxœdema and cretinism, while results in pituitary disorders had been obtained by X ray applications and glandular feeding. Malarial treatment, successful in many cases of general paralysis, had not yet been found to influence dementia præcox nor epilepsy. Both diagnosis and treatment demanded that investigation of the autotoxæmic influences in psychoses should be regarded as one of the most important researches in psychiatry.

Dr. F. A. Pickworth (Birmingham) brought forward some work which was being done in Birmingham in connexion with the joint Board of Research for Mental Diseases and the Birmingham Mental Hospitals. The question of focal and intestinal sepsis had been studied very carefully. They had found evidence of infection with organisms of the paratyphoid and food-poisoning groups which was considered to have a causal relation to focal sepsis variation in agglutinin response and metabolic disturbance. A special study had been made of the relation of sinusitis of the sphenoid to pituitary disturbance, and pituitary dysfunction might explain some of the symptoms of endocrine deficiency. Dr. Pickworth showed slides illustrating: (1) the sphenoid sinus containing pus, and demonstrating that the pituitary gland had very little protection from the organisms and toxins which invaded the damaged epithelium; (2) a perforation into the pituitary fossa from a sphenoidal sinusitis. Other slides illustrated actual infection of the pituitary fossa, and one showed a number of organisms in a large mass of colloid in the pituitary capsule, suggesting that abnormally large masses of colloid in the pituitary had relation to septic involvement of the gland. Given septic involvement of the pituitary, it was reasonable to suppose that septic products, or at least a perverted pituitary secretion, was able to reach brain tissue.

Dr. E. Mapother (London) thought all were equally agreed that every mental process was only the subjective aspect of a bodily one which left traces and originated habits and reactions. As regards gross endocrine abnormalities and mental disorder, Dr. Mapother thought that the evidence suggested that in most cases, with the possible exception of the thyroid, the association was rather one of frequent occurrences than of causal dependence. He had known dystrophia-adiposo-genitalis coexist with perfect mental normality; similarly, giantism was only occasionally associated with mental defect. Concerning genital glands, he thought that, if we interested ourselves in evidence of functional disturbances rather than gross anatomical changes, the history given by many patients was significant. Sexual disturbances and the psychological reactions arising therefrom, appeared of more psychiatric importance than all the rest of the endocrine disorders. Such conditions as erotism and nymphomania on the one hand, impotence and frigidity on the other, were extremely common, and the reactions arising from these conditions were most important.

Dr. I. S. Wile (New York) considered that the terms toxæmia and psychoses were employed in too broad a sense. They could not disregard heredity, infections, &c. Endocrine disorders and psychoses might be due to a common underlying cause, such as syphilis; concomitant as in association with cerebral tumour and diabetes; or in causal relation as mental enfeeblement and athyroidism. It was necessary to show causal relationship rather than coexistence of symptoms. At present all phases of study were essential to secure material facts from which later generalisations might be made. For many years it would be advisable to accumulate data regarding heredity, infection, trauma, and metabolism. Equally important were the appreciation of the psychological and psychogenetic factors entering into psychoses in relation to toxæmia.

Dr. Mary Barkas (London) advanced the view that the association of physical disorders with mental disease might be explained otherwise than as direct causes, and that the psychiatrist might promote the development of psychiatry far more by concentrating on the study of the mental processes of patients than by a flight into the laboratory. Dr. Barkas thought that plausible explanations of the association of bodily manifestations with psychosis could be offered. She believed that autotoxæmia and similar disorders might be related to mental disorder in the following ways: (1) as a precipitating factor; (2) as a source of mental stress; (3) as joint effect of some primary cause; (4) as chance concomitant; (5) as result of the mental and emotional or psychomotor disorder. It must also be remembered that while they were dealing with those cases of disordered bodily function which were insane, there remained in the general population far larger numbers suffering from similar disorders, but free from mental illness; the speaker held that it was for them as psychiatrists to investigate what were the other factors, lying perhaps in the inherited constitution and temperament, in the individual development of personality, or in the foregoing emotional situation of their patients, which had determined the mental breakdown. The physical disorder might have been the last straw, making a pre-existing burden of a stress intolerable, and its removal might make readjustment possible. Various endocrine defects might produce dwarfism, but many dwarfs were of quite normal mentality, notably achondroplasics, and some forms of pituitary infantilism. Where they were mentally abnormal, might we not equally well suppose that their mental symptoms were a reaction to their bodily abnormality, which produced a sense of inferiority or an attempt to over-compensate for this, cunning or suspiciousness, and an attitude of defence to make up for lack of physical strength, and a whole series of other mental reactions. Until we had studied these mental phenomena in sane and insane alike who laboured under endocrine disorder, we were not in a position to assert that mental symptoms, when found, were directly produced by the metabolic dysfunction.

Dr. R. D. Gillespie (London) said that the conception of autotoxæmia in this country had been restricted largely to conditions of supposed intestinal absorption. The bacteriology of the colon in persons mentally *normal* was in too vague a condition to make it safe to draw definite conclusions from a bacterial examination of the fæces in the psychoses. Similarly, regarding Dr. Pickworth's observations, it was

CIVILIANS AND BOMBARDMENT FROM THE AIR.

THIS week's manœuvres over London and the home counties seem to show that complete protection of a large city from aerial attack is at present impossible. It is a military axiom that means of defence never lag far behind means of attack, but for the moment, given equal forces, there is evidently no way of preventing a capital city from suffering severely by bomb-fire. The contents of the bombs to be used in true warfare are a matter of conjecture, but there is little reason to doubt that poison gas would be freely employed, and it may be of interest to recall the steps that are recommended to neutralise its effects. These were set out recently before the Academy of Medicine in Paris by Inspector-General Sieur,[1] who summarised a scheme agreed upon by the International Red Cross for the protection of civilians. This scheme was drafted in 1925 by a committee of experts—chemists, engineers, doctors, administrators, and workmen. Recognising that it is impracticable to supply everyone with individual protective apparatus of the best kind, it divides the community into two classes, active and passive. Active members—police, firemen, first-aid workers, and the like—receive the best possible equipment; passive members are given cheaper and more simple appliances which may safeguard them under ordinary conditions, but they must chiefly rely on being protected collectively. As a gas attack is likely to include attack by explosives, small bomb-proof shelters should be made to accommodate not more than a dozen persons. Any room, it is stated, can be rendered proof against non-lingering gases by hanging its openings with fabrics steeped in appropriate solutions or specially prepared, but it is better to use tightly fitting panels and maintain, by means of artificial ventilation, a pressure slightly above that of the surrounding atmosphere. The air should be taken from as great a height as possible and filtered mechanically and chemically; in shelters to be occupied by children or the sick and aged there should be a supply of oxygen. Shelters are best established in cellars, and there should be a stout layer of impervious flag-stones or concrete flooring over each, and where possible on each floor of the building. Besides these refuges there should be first-aid posts, special hospitals, and means for the transport of injured persons. Lingering gas imposes a serious problem, as it is highly poisonous and may contain pathogenic organisms. All places contaminated should be immediately cleared of their occupants and disinfected, and the occupants should be taken for bathing and disinfection to special stations, and should be excluded from ordinary shelters. Food and drinking-water should be protected, and municipal water-supplies should be covered with an impermeable mineral flooring, whilst gas and electrical conduits should be guarded against explosives. These provisions, said Dr. Sieur, should all be made in peace-time by committees of military and civil authorities, with representative citizens, for each district. The first-aid corps—in this country presumably composed of ambulance workers and trained volunteers—should be distinct from the disinfecting corps, which should be supplied by the fire brigade where there is one, and recruited from volunteers and local sporting organisations where there is none. He states that the British Red Cross is already training its personnel on these lines, but obviously the population here is wholly unprepared for a modern air-raid, whilst neither individuals nor municipalities are likely to plan their undertakings with aerial warfare in view.

GIFT TO RADCLIFFE INFIRMARY.—Mr. W. R. Morris, the motor manufacturer, has given £38,000 for the building of a new maternity home at this hospital. He is the President of the Governing Body.

BRITISH MEDICAL ASSOCIATION.

ANNUAL MEETING AT CARDIFF.

(Continued from p. 302.)

SECTION OF MENTAL DISEASES AND NEUROLOGY.

AUTO-TOXÆMIA AS A FACTOR IN THE CAUSATION OF PSYCHOSES.

Prof. W. WEYGANDT (Hamburg), in opening the discussion, pointed out that with the advance in the pathological anatomy of the central nervous system, it had become more apparent that mental derangements were cerebral diseases, and that a morbid influence on the brain was the cause of mental disorders. The biological investigation of mental derangements was all the more important as the morbid anatomy of the brain had not fulfilled expectations, nor had experimental psychology or psychoanalysis led to very definite results. Prof. Weygandt then considered in detail the forms of retarded development in relation to metabolism of the endocrine glands. Disturbances of the thyroid gland in childhood led to retarded growth and delayed or absent sexual development as well as to mental retardation. Treatment with thyroid relieved such symptoms; excellent results were also obtained in myxœdema. In Graves's disease removal of a portion of the gland by operation was an important procedure, but thymus and ovarian preparations had also been employed. The speaker referred to the fact that giantism and acromegaly were sometimes associated with idiocy, in addition to Fröhlich's syndrome. In such cases a primary disorder of the cerebral cortex was presumably present.

Prof. Weygandt considered that the thymus had also a relation to mental evolution. Klose had removed the thymus in young dogs and observed that the animals developed obesity and ceased to grow, became stupid, tried to eat wood and stones, and eventually died. H. Vogt had described thymic idiocy in a dwarf, aged 17, with flabby muscles, fragile bones, general tremors, and retarded general development. As regards the suprarenal glands, Addison's disease was sometimes associated with headache, depression, fatigue, insomnia, and deficient memory. Strictly speaking, there was no such condition as an uniglandular disorder, for after the loss of one endocrine gland, changes in the other glands would occur. In mongolism the physical signs were those of retarded development, and might be associated with signs of thyroid or pituitary deficiency. Kafka had shown that the serum in most cases gave a weak but distinct "decomposition" reaction (Abderhalden) of the pituitary gland. Also, the white blood cells were increased, while the viscosity of the blood plasma was decreased. Prof. Weygandt considered that mongolism was not syphilitic in origin. One of the most important problems in psychiatry was to determine the pathogenesis of dementia præcox (schizophrenia). Pathological changes had been found in certain cerebral cells, especially those of the third stratum of the cortex. The fifth and sixth strata might also show atrophic changes. The contention of Mott that degeneration of the spermogenic cells and Leydid cells was the basis of the disorder was not generally admitted. Prof. Weygandt considered that endocrine degeneration, as shown by Abderhalden reactions, was most important, although many held these reactions in doubt. If a disorder of metabolism, and especially of the endocrine organs, affected a brain rendered somewhat abnormal by heredity, conditions were favourable to the development of schizophrenia. Entirely different, in Prof. Weygandt's opinion, were the basic conditions of manic-depressive psychosis (cyclothymia). The inherited factor in this disease was paramount and could be traced in 90 per cent. of cases. There appeared to be no question of signs, it was often difficult to distinguish them from those of an anxiety state. Of particular importance in the differential diagnosis was the character of the headaches and their relation to posture. In neurosis the headache was continuous rather than intermittent, had little or no relation to posture, and was aggravated by mental stress. In true contusion the headache might be associated with giddiness, also related to posture, retardation of mental processes and defective memory for recent events were valuable signs of cerebral damage. It was important to remember that the brain might be severely damaged without fracture of the skull or objective physical signs, and that, conversely, fracture of the skull was not in itself proof of cerebral injury. The signs of subdural hæmatoma were often those of cerebral tumour—papillœdema, hemiplegia, &c.—and the cerebro-spinal fluid might exhibit xanthochromia and fibrin flakes.

As regards treatment in major contusion, relief of intracranial pressure might be obtained, either by lumbar puncture repeated at two-day intervals, if necessary, or by intravenous injection of 50–100 c.cm. of 15 per cent. hypertonic saline. The effect of this latter was to cause shrinkage of the brain by absorption into the blood stream of extravascular fluid contents. The effect was temporary only and the procedure might have to be repeated at intervals of two days. An alternative method was to give a saturated solution of magnesium sulphate (3 oz. in 6 oz. of water) by the rectum; to be effective, this solution should be retained for half an hour. In a series of 80 patients with symptoms of cerebral contusion Dr. Symonds found that 18, or 22·5 per cent., stated that they had made a complete recovery. In cases of major contusion the chances of the patient being able to return to full work were less than 1 in 3, and there was the same chance of total incapacity. In cases of lesser injury, there was an even chance of the patient being able to return to full work, and a very small risk of total incapacity.

Dr. C. **WORSTER-DROUGHT** (London) entirely agreed with Dr. Symonds in his statement that the brain might be very seriously damaged without fracture of the skull, or indeed, evidence of bone injury. In assessing the effects and possible consequences of head injury, far too much stress was laid upon the radiographic appearance of the skull, and if negative, the cerebral injury was often assumed—not only in legal, but also medical circles—to have been slight.

In his experience, the after-effects of what has been described as major contusion were more often severe than not—and personally he would not have placed the rate of complete recovery in these cases as high as 22·5 per cent. Cerebral contusion might lead to localised adhesions between the dura, arachnoid, and cerebral cortex and so give rise to epilepsy—and all without X ray evidence of bone damage. This was strikingly illustrated in one case that came under his observation—a case also noteworthy on account of the excellent result of surgical treatment. A man, aged 28, fell, striking his head on the junction of two tram lines. Three years after the accident his first epileptic fit occurred, there being no previous history of epilepsy. Examination showed a scar in the supra-occipital region, but no other physical signs.

The region of the scar was trephined, and when the piece of bone was removed, the dura on incision was found to be adherent to the underlying cortex. Dr. Worster-Drought had had this patient under observation since the time of operation—six and a half years—and no further epileptic attack had occurred; the patient returned to work and was in excellent health. Equally successful was another case of traumatic epilepsy, due to a lesion that might be described as unusual form of subdural hæmatoma in the posterior parietal region. An interesting point was how long after a head injury could epilepsy appear? In his experience, it had been common for epilepsy to appear three or four years after the accident, and he had met with cases in which the first epileptic attack had occurred 10 and even 12 years after the head injury. As regards treatment of traumatic epilepsy, the conclusion was that in the presence of definite evidence of the site of injury, such as a scar, &c.—even if radiographic appearances were negative and in the absence of other localising physical signs—operation was worth while. He would not advise operation in the absence of physical signs or of some evidence indicating the site of injury. The mental sequelæ of cerebral contusion were often peculiar. One somewhat unusual effect was complete and apparently permanent inability to perform mental work, of which Dr. Worster-Drought gave examples.

Dr. Worster-Drought considered that head injuries in the left frontal region were the most serious as regards prognosis in respect of mental changes. A condition of dementia might result from damage in this situation. He had seen such cases, and one example he described. In view of the fact that W. E. Dandy, in America, had recently excised the right cerebral hemisphere in man without, it was reported, the patient showing evidence of mental change, such injuries to the left frontal region were of interest in its possible localisation of the main seat of intellectual activity. As regards treatment, Dr. Worster-Drought was not convinced of the practical value of intravenous injection of hypertonic saline. The relief of symptoms afforded was somewhat uncertain and transient. He mentioned experiments supporting this contention. He was inclined to regard lumbar puncture, repeated if necessary, as the best means of relieving intracranial pressure. The continued administration of saline substances either by the mouth or rectum might, however, also be of value. For chronic and persistent headache following head injury, when repeated lumbar puncture failed to give permanent relief, Dr. Worster-Drought was in favour of sub-temporal decompression. He had seen several cases in which this operation had given excellent results.

Dr. **WILE** remarked that in children cerebral contusion might lead to changes in personality accompanied by delinquency and epileptic equivalents, resembling some of the sequelæ of encephalitis lethargica. It was necessary carefully to distinguish the headache, giddiness, and various mental disabilities following minor contusion from psychoneurotic symptoms. It was important to apply psychological tests in determining defects of memory, whether visual or auditory, for recent or remote events. The relation of cerebral injuries to later educational disabilities could only be determined by more thorough psychological investigation. Traumatic neuroses might be exaggerated in frequency, but it is wise to be certain that minor mental symptoms were not functional before suggesting that they were the residua of organic disease or cerebral injury. He agreed that emphasis was necessary upon the statement that fracture of the skull was not proof of cerebral damage, and that, conversely, damage of the brain might exist without a fracture of the skull. In order to interpret the actual state of a patient following cerebral injury, it was necessary to know if he returned to his earlier occupation, or was subject to further re-education, or was obliged to change by reason of changing industrial conditions.

Dr. **GILLESPIE** said that the classical psychotic syndromes had no definite ætiological relationship to trauma, and certifiable insanity rarely occurred as the result of head injury. In some cases that had been recorded other factors had been prominent, such as alcoholism, and heredity. Several forms of late after-effects could be distinguished, including traumatic mental enfeeblement and behaviour disorders. The chief difficulty arose in the diagnosis of these defect-states from those of psychoneurosis; nevertheless definite criteria existed, such as slowing of thought, attention defect, and mood disorders. Also the dangerous for him to argue from his interesting findings to the psychoses in general. Regarding intestinal toxæmia, clinical experience with Hirschsprung's disease showed that mental symptoms were usually absent in spite of the extreme intestinal stasis. Ulcerative colitis, in which toxic absorption certainly occurred, was not, as a rule, accompanied by mental changes, whereas mental symptoms often accompanied so-called mucous colitis, in which absorption was probably absent.

Dr. **Helen Boyle** (Brighton) looked at patients from the clinical side: What was the matter with them? What would cure them? How long would it be? It was encouraging that Prof. Weygandt mentioned recovery in dementia præcox, and clinicians would agree with him that some such cases appeared to recover. His paper suggested a hope that some test might serve to differentiate these cases from others. It was not satisfactory to assume merely that should recovery occur, the diagnosis was wrong. With regard to manic-depressive states, Dr. Boyle said that many patients seemed to show an association with Graves's disease. This was more obvious in the early stages, but even in confirmed cases the description of excitement, tendency pyrexia, rapid pulse, sweating, and other symptoms suggested hyperthyroidism. There was not infrequently an enlarged thyroid. When this phase subsided, the picture often suggested hypothyroidism—as though the thyroid was fatigued and could do no more. There was depression, weight increased, the patients were slow and weary, with lack of interest, and in exactly the reverse of their previous states.

Dr. **E. Goodall** (Cardiff), the President, remarked that many acute and recent cases of mental disorder improved in large measure with a preliminary enema or colonic lavages. In Cardiff they had published from the Mental Hospital laboratory work upon the distribution of the various nitrogen constituents of plasma, cerebro-spinal fluid, and urine in some 40 (mostly recent) cases of mental disorder, and the results appeared to point to anomalies of protein metabolism. With regard to blood chemistry, the methods for the estimation of blood substances were at present far from adequate. Reliable methods for the estimation of glucose alone had still to be elaborated; also with cholesterol, the statements published regarding a diminution or excess of blood cholesterol in epilepsy and at the menstrual period were unreliable. Some 15 years had passed since Fauser published his results with the Abderhalden reaction in cases of dementia præcox and other mental disorders. His results at that time were mainly confirmed, and there seemed to be evidence that a positive reaction was obtained by Abderhalden's method with cerebral cortex and gonadal tissue in dementia præcox. Of late years one had heard and read little or nothing of the Abderhalden reaction in psychiatry, so that it was of interest to hear Prof. Weygandt's opinion that this method gives a positive result as regards blood and cerebro-spinal fluid in dementia præcox, not only of cerebral cortex and gonads, but often with thyroid and pituitary. If this were so, a means of diagnosis between true dementia præcox, and other mental conditions resembling it, should be established. The difficulty of carrying out the test no doubt accounted for its general non-employment.

Cerebral States Consequent upon Head Injuries.

A discussion on the differential diagnosis and treatment of these states was opened by Dr. **C. P. Symonds** (London). Apart from the immediate surgical risks of compound fracture, rupture of a meningeal artery, and subdural hæmatoma, the severity of head injury varied according to the nature and amount of damage sustained by the brain at the time of injury. When such injury did not prove fatal, there would result cerebral symptoms the differential diagnosis and treatment of which the speaker proposed to discuss. Concussion might be defined as a condition of subtotal cessation of cerebral function following immediately upon an injury, with subsequent complete recovery within 24 hours, at the end of which, in an uncomplicated case of concussion, recovery should be complete. The symptoms were probably due to temporary vascular embarrassment. Distinct from concussion, though often associated with it, was the condition of cerebral contusion. The symptoms of cerebral contusion depended upon two factors: (1) the effect upon intracranial pressure, and (2) the site of the lesion. The focal signs of the latter were those of cerebral disease generally. The effect upon intracranial pressure depended upon the amount of hæmorrhage and exudation. For the purposes of clinical description, Dr. Symonds distinguished between a major and a minor degree of contusion. The major form was almost always associated with concussion; after a few hours the patient partially regained consciousness, but instead of progressing towards normal, he remained stuporose, restless and irritable and might be noisy, hallucinated and even violent. This condition might persist for some days or weeks, the tendency being towards gradual improvement. Lumbar puncture and the application of a manometer might show the presence of increased intracranial pressure; the cerebro-spinal fluid might be blood-stained, indicating capillary hæmorrhage. In minor contusion, the injury might or might not cause concussion. It was possible for a glancing blow to contuse the brain, without loss of consciousness at the time of injury. Symptoms might follow directly upon the injury, but more usually developed after a latent period varying from hours to weeks. The three symptoms most constantly present were headache, giddiness, and mental impairment. A characteristic feature of the headache was its relation to alterations of posture. The mental symptoms consisted of defective memory, inability to concentrate, decreased emotional control, and mental fatigue. Apart from focal physical signs which were rarely encountered, there were other conditions such as epilepsy and permanent mental change which must be related to local damage. Minor degrees of mental impairment—e.g., memory defects—were frequent, but permanent mental deterioration necessitating institutional treatment appeared rare. Epileptic atacks might occur even in the early stages of a major contusion and were probably due to subarachnoid hæmorrhage; attacks developing after a latent interval of months or years were of more serious significance. Cerebral abscess following a compound fracture, and chronic subdural hæmatoma, although both rare, were two sequelæ of head injury which the neurologist was likely to encounter. In subdural hæmatoma the patient began to complain of headaches usually several weeks after the original blow. Other symptoms of intracranial pressure gradually appeared, with stupor and finally coma. Owing to the long latent period and possibly trivial nature of the original injury the diagnosis was sometimes mistaken. The cerebro-spinal fluid might be found to contain altered blood-pigment and flakes of fibrin. Finally, there was a considerable number of cases in which the disability following head injury was wholly or partly of a neurotic nature and usually based upon the problem of compensation.

As regards diagnosis, Dr. Symonds said that during the first 24 hours it was impossible to make a comprehensive diagnosis owing to the state of concussion masking what lay behind. If, however, after partial or complete recovery of consciousness the patient sank again into true coma, or paralytic signs developed, arterial hæmorrhage was almost certainly present. The absence of concussion did not exclude the possibility of symptoms of contusion or subdural hæmatoma developing at a later stage. Stupor and irritability after the first 24 hours indicated major cerebral contusion. A patient might apparently recover and yet develop symptoms of minor contusion after several weeks. Since the symptoms of minor contusion were as a rule unassociated with physical

Early Treatment of Psychosis in Psychoneuroses.

Dr. Helen Boyle (Hove) said that the discussion divided itself naturally into two parts: (1) the early treatment of the individual, and (2) how we could best obtain it. It must be recognised that insanity began before a person was insane. Many, if not most, of the difficulties met with in education, criminology, religion, industry, and general medicine, could only be solved with the aid of mental medicine—an understanding of the mind of man, in health and disease. No doctor would admit that an understanding of the body in health was foreign to his purpose of grappling with disease. No doctor should any longer admit that an understanding of the mind in health was redundant, and still less of the mind diseased. The intricacies of its connexion with the body still needed further elucidation. The early treatment of recent cases in mental hospitals had improved immensely of recent years. The hospitalisation of asylums was progressing apace, but she wished to consider not the certifiably insane treated in mental hospitals, but the patients whom it was harmful to certify or who were uncertifiable, the large number of the maladjusted, the patients labouring under obsessions, phobias, inhibitions, and so on. These were the cases for whom early treatment was so necessary if they wished to prevent the faulty adjustments, criminals and others. Dr. Carswell was the pioneer who started wards for borderland patients in connexion with the poor-law, Dr. Boyle believed, in 1904. The Lady Chichester Hospital was the first hospital for these cases, and started in 1905. The pioneer in providing out-patient facilities was the late Dr. Rayner, who with energy and foresight, about 1889, induced the governors of St. Thomas's Hospital to open an out-patient department for early mental cases. Since then, many others had followed suit.

Still earlier than those cases they had been considering were the children who show maladjustments in school life or before, and for them the child guidance clinics offered useful help. They are, as before stated, the first line of defence. Two are already in existence in England, and an elaborate one in London is being planned with American help.

Finally, Dr. Boyle said that she would suggest that it was desirable: (1) that every general hospital should have facilities for treating early nervous and borderland patients; (2) that child guidance clinics should be available for the young maladjusted children and be under the charge of doctors; (3) that delinquents should have expert examination with regard to their mental adjustment—on the first offence—repeated if necessary; (4) that voluntary boarders be allowed in county mental hospitals; (5) that early insane patients should be able to be treated on two doctors' certificates; (6) that vocational guidance should be available for all who wish it—as at the National Institute for Industrial Psychology—as a preventive measure against maladjustments and unrest; (7) that every medical student should be obliged to devote some time to the study of all forms of mental disorder; (8) that examining boards should require evidence of knowledge of all forms of mental disorder. It was better to pay for this than for insanity, delinquency, unemployment, and industrial unrest.

Prof. Weygandt said that one of the chief difficulties was the recognition of pre-morbid cases. In the commoner types of mental disorders there was an inherited predisposition—e.g., schizophrenia, cyclothymia—and even in early youth latent symptoms might exist. These it might become possible to detect by biological and psychological methods. There had already been several attempts to investigate children liable to mental disorder. At Hamburg they had a clinic for the observation and treatment of psychopathological boys by specially trained medical men and teachers.

Dr. Wile said that the prevention of psychoses and psychoneurosis should be undertaken in childhood to be adequate. From experiences at his own clinic at the Sinai Hospital, New York, he had found that much of the work could be carried out in an out-patient department. The problems met with could be classified under the following headings: (1) social maladjustments, which grew out of social nonconformity; (2) inadequate and undesirable habit-formations—e.g., insomnia and night terrors; (3) personality trends—e.g., timidity, selfishness, and seclusiveness.

Dr. Mapother agreed that in smaller country towns an out-patient department or a ward might be all that was attainable, but it did not follow that such an arrangement was the ideal. In advocating the psychiatric clinic wherever possible as against the policy of a ward or department in a general hospital, he laid stress on points: (1) that it was wise not to rationalise into laws of nature restrictions and separations and vested interests which had really grown up from the absurdities of the Lunacy Act of 1890; (2) the tendency of every progressive country in Europe was towards establishment of special clinics; (3) detailed knowledge of attempts in Great Britain to establish psychiatric treatment in general hospital wards was evidence of their inadequacy.

Dr. Barkas said that it was too often assumed that early and recoverable cases were necessarily mild ones, not needing the resources of a mental hospital for their treatment; this was far from being the case, for it was just those eminently recoverable acute cases who broke down rather suddenly, without such prodromal signs as were likely to be noticed, who formed the group in which prognosis was best, while those of more insidious onset were, unfortunately, quite often the most intractable. An extension to all patients of the provisions now available for private patients, with adequate supervision by the Board of Control, a thing no general hospital was likely to welcome, would do much to supply all that was needed for the present. Child guidance clinics had shown how greatly the problem of the psychopathic child was bound up with social considerations, and how all-important was the social worker in the re-education of the family. The same applied to the adult neurotic; and Dr. Barkas believed that no clinic for either in- or out-patient treatment would be able to do satisfactory work unless it included a well-trained staff of social workers who could deal with the environment of the patient.

Dr. R. G. Gordon (Bath) considered that an intensive study of the personalities of individuals was necessary whether sound or sick, and that particular attention should be paid to the capacity and success enjoyed by adjustments to environment. If this was done he suggested that it would be found that the person who under certain conditions, whether of toxæmia, endocrine disturbance, mental conflict or emotional shock, broke down into a psychosis, differed in his "personality make-up" from another patient who under similar conditions developed a neurosis. Moreover, he would suggest that one of the chief differences was, that in the first case the personality had no real tendency to adjust to the environment, and that in the present state of our knowledge our efforts scarcely increased this adjustment. With greatly increased knowledge we might be able to foresee that under certain circumstances which might be avoided. "A" would break down into a psychosis of a particular kind, say manic-depressive insanity; "B" into a psychosis such as dementia præcox, and so on; while "X" would break down into a neurosis of a certain kind, say, an anxiety state; and "Y" would develop hysteria, and so on. He could not affirm too strongly that this was an ideal situation, and that at present probably no one pretended to be able to carry out such subtleties in diagnosis; yet increasing experience seemed to be pointing that way.

patient should invariably be considered as a whole, especially his previous personality.

Mr. **Wilfred Trotter** (London) said that until recent years a whole train of symptoms following head injury had been regarded as vaguely due to hysteria, malingering, &c., but that such symptoms had been brought under scientific observation and were no longer so vague and indefinable. It was possible to distinguish as precisely as anything in medicine a form of amnesia that was characteristic of true concussion. This was retrograde amnesia—a loss of memory for events preceding the accident, the patient having no recollection for anything that occurred during the 15 to 20 minutes that preceded his head injury. A further point of importance in diagnosis was that in the headache following minor contusion the patient when free from such headache felt perfectly well; this was not the case with the psychoneurotic.

For intractable headache following minor contusion a decompression operation was indicated. In major contusion, Mr. Trotter doubted if one was justified in leaving the brain in a seriously congested condition over a long period. He advocated the special operation of making a small opening in the skull to interrupt the vicious circle of compression.

Dr. **D. McAlpine** (London) confined his remarks to the question of treatment. Increased intracranial tension was brought about by traumatic œdema or hæmorrhage, or a combination of both. Œdema resulted in a general enlargement in the size of the brain which tended to bring its surface close up against the dura. The effect of this was to hinder in varying degrees the absorption of the cerebro-spinal fluid into the venous sinuses, but as the cerebro-spinal fluid continued to flow from the choroid plexuses and accumulated in the ventricles and basal cisternæ, more and more pressure was brought to bear on the medulla until it became paralysed. In some cases, therefore, traumatic œdema resulted in death from medullary compression, and this was a fact that could not be overlooked from the point of view of treatment. Lumbar puncture afforded an easy means of reducing the tension, and was practically free from danger in cases of head injury, excepting in the stage of shock. As long ago as 1905, Quincke pointed out that in brain injuries the estimation of the cerebro-spinal fluid pressure was of importance, and that the best results were obtained by drainage. Until recently little importance had been paid to the principles underlying this observation. A rise of blood pressure accompanying intracranial tension was true only of the late stages of medullary compression, and should not be relied upon as an early sign. The only sure guide to the tension of the cerebro-spinal fluid was the manometer. The normal reading of the cerebro-spinal fluid pressure lay between 6 and 8 mm. of mercury. When the stage of shock following a head injury had passed, and no immediate surgical interference was called for, lumbar puncture should be performed and the tension of the fluid measured. If this was raised, sufficient fluid should be allowed to drain away until the tension was reduced to just below normal. The puncture should be repeated at the end of 12 hours in any case of severity, and performed daily until the tension returned to normal. If after two or three punctures it was found that the tension was increasing, then the possibility of cerebral decompression should be considered.

Dr. **G. Riddoch** (London) said that it was important to separate anxiety states from those of post-traumatic defect. The latter were of the order of a mild dementia—deterioration of general mental capacity. The patient's symptoms tended to become worse towards the end of the day, whereas in anxiety states the symptoms were usually most pronounced in the morning. The symptoms were mainly those of lack in mental and physical efficiency and were an indication of the effect on the brain as a whole rather than a sign of local contusion. Mr. Trotter had suggested the term "post-contusional submentation" to indicate this condition. Dr. Riddoch considered that hypertonic saline was of value in relieving intracranial tension, but that the method should be used with discrimination; it should be given preferably per rectum.

Dr. **E. Mapother** (London) was surprised that various speakers whose experience of head injury was larger than his own should have found acute and severe psychoses so rare a sequel of head injury. He described three such cases directly following severe motor-car accidents. The salient feature in all three was a manic state, a joyous satisfaction with self and circumstances and disjointed hyperactivity. This was associated in a manner that one did not see in ordinary mania with confusion. Disorientation and amnesia for current events was also present; in fact, all three cases somewhat resembled a combination of mania with Korsakow's syndrome. All the patients recovered within a few months. Their condition was certainly not of purely emotional origin, and the patients had never shown previously a neurotic or psychopathic disposition.

Dr. **Pickworth** said that the connexion between head injury and mental disease was found in local or general cerebral anoxæmia or the results consequent upon inadequate removal of metabolic waste products. There was a remarkable similarity in some of the mental symptoms which might occur in chronic subdural hæmorrhage, simple anoxæmia and anoxæmia produced by carbon monoxide poisoning. Almost any symptoms of mental disorder might be reproduced by this condition. A history of head injury was by no means rare in mental hospitals.

Mr. **Geoffrey Jefferson** (Manchester) added his testimony to the importance of the condition of retrograde amnesia which Mr. Trotter had mentioned. Another point was the anatomical basis of contusional states, be they recent or remote. Histological study of fatal cases showed minute though widespread change. He believed that lesions of a similar but lesser degree existed in those patients who finally recovered. The outstanding feature of the finer changes in the brain tissue was cerebral œdema, so that the perivascular sheaths were distended or ruptured. The question of treatment was based largely on pathological anatomy and its physiological results. If gross hæmorrhage was present the treatment was obvious. It was the œdematous cases which presented the chief difficulty. A great change had occurred in the surgical treatment of head injuries, a change from indiscriminate surgery to one of almost complete conservatism. Mr. Trotter had done a service in voicing his doubts as to whether they were right in allowing patients to lie for long in a condition of restless unconsciousness, and there could be no question that judicious surgery held a place in treatment. If one could be sure that the brain was œdematous, hypertonic solutions (and 50 per cent. glucose rather than saline was preferable) should succeed. But if a temporary improvement was followed by relapse, decompression should be done.

Dr. **R. Fager** (Exeter) stated that during the war he had had the opportunity of studying a large number of cases with mental symptoms of varying degree following head injuries. Headache was an almost constant and distressing symptom; usually, but not invariably, it was referred to the site of injury, and was aggravated by stooping. The pain might be so depressing in character that the patient sought refuge in alcoholic bouts and even suicidal attempts. Other common symptoms were restlessness, irritability, lack of concentration, and even hallucinations.

Epilepsy occurred four times more frequently in severe injuries than in those of a superficial character. Cases in which memory defect was a conspicuous feature were mainly in the frontal region, but there appeared to be no relation between the degree of amnesia and the severity of the injury. Mental symptoms were the direct result of the head injury in a small proportion of cases.

instances of non-tuberculous conditions such as tabetic spine, chronic traumatic arthritis, Kümmell's disease, Perthes's disease, *pied forcé*, fibro-sarcoma of the femur, &c. He illustrated these and other conditions by a series of lantern-slides. In conclusion, he said that injury to a tuberculous joint did lead to recrudescence of the disease, but emphasised his opinion that trauma was not a common cause of tuberculosis in cases where a quiescent focus had not previously existed.

Dr. Otto May (Prudential) dealt with the matter from the point of view of accident insurance. He agreed with most of Dr. Tattersall's statements. Mr. Milne, he said, had shifted the discussion to another plane, and had maintained that we must question the diagnosis of traumatic tuberculosis in nearly every case. But the employer is still liable for compensation claims whether the condition is tuberculous or not, so that, in compensation cases, the exact diagnosis was not really a matter of first importance. Dr. May classified traumatic tuberculosis for the purposes of accident insurance and compensation under four headings: (1) recrudescence of a pre-existing focal lesion; (2) miliary tuberculosis following trauma at the site of a tuberculous focus of disease; (3) tuberculosis arising at the site of an injury without a history of previous tuberculosis; and (4) cases in which pulmonary tuberculosis arises after an injury to some other part of the body. In a court of law, he said, one can only give an opinion as to the possibility of the accident having caused the disease, but provided that one did not assume the pose of pontificial infallibility, a touch of dogma was of more practical help in the dispensation of justice than the cleverest exposition of scientific agnosticism.

During the discussion which followed the reading of the papers, Sir Robert Philip (Edinburgh) suggested two practical points in dealing with accident cases. In the first place, a series of radiograms of the affected parts and of the chest should be taken at short intervals and, secondly, many patients had cause to bless the accident, because it brought a smouldering tuberculous focus into view, and by early treatment and the care that was taken in compensation cases, many valuable lives were saved. —Dr. Alexander Brownlee (Cardiff) thought that the percentage of cases following injury was higher than the figures given by Mr. Milne. In a series of his own cases he had found 32 per cent. of cases of hip disease, 33 per cent. of spine cases, 22 per cent. of knee cases, and of other joints 25 per cent. gave a history of injury. He agreed that it was doubtful whether trauma to a previously healthy person could set up tuberculosis in the injured part, but thought that probably the majority of the population was pathologically, although not clinically, tuberculous. "Bridge" symptoms were important in compensation cases, especially if occurring within six months following injury to the knee, within 12 months after trauma to the hip, and in the case of the spine, within two years. However, one could not dogmatise on this point.—Dr. Cecil Wall (London) said that repeated multiple minor traumata, fatigue, and mental anxiety could all help in the activation of a dormant tuberculous focus. There was little difference, he said, between minor multiple traumata and fatigue.—Dr. James Crocket (Glasgow) regarded both mental and physical strain as instrumental in exacerbating tuberculosis.—Dr. H. V. Cantor (Cheshire Joint Sanatorium), in discussing tuberculosis following war injuries, said that the Ministry of Pensions did not consider claims in cases diagnosed as tuberculous within the last two years.

Dr. Tattersall, in reply, said that he was gratified that a blow had been struck against the theory that tuberculosis was implanted on injured previously healthy tissues. In reply to Dr. Cantor, he said that the Ministry of Pensions had been very generous in their treatment of ex-Service men.—Mr. Milne did not agree with Dr. May that the diagnosis was not important in compensation cases. He regarded it as essential both from the point of view of treatment and of compensation.

Factors in the Biochemistry of Tuberculosis.

Dr. L. S. T. Burrell (London), in reading a paper on the therapeutic value of the heavy metals in pulmonary tuberculosis, referred briefly to the use of copper and lead, and to the reactions following the use of such metals as well as of other shock-producing agents such as serum, tuberculin, protein, sun rays, &c. In the use of gold, and especially of sanocrysin (double thiosulphate of gold and sodium) he emphasised the point that the reaction following an injection was similar to that produced by the other shock-producing agents, but that it differed from them in its effect, in that the reaction was followed by the disappearance of tubercle bacilli from the sputum, and by diminution in the amount of sputum. The chief indications for the use of sanocrysin were (1) in cases where the amount of sputum containing tubercle bacilli persisted in spite of other forms of treatment, and (2) in cases of bilateral disease, where it could be used in conjunction with artificial collapse of the more extensively diseased lung. He usually commenced with a dose of 0·1 g. followed three days later with one of 0·25 g. Then, at weekly intervals, he gave doses increasing from 0·5 to 1 g. until the patient had had 5 or 6 g. The complications, such as albuminuria, a metallic taste in the mouth, stomatitis, erythematous rashes, and febrile reactions, had not been serious or of frequent occurrence. In conclusion, he said that he regarded sanocrysin not as a specific against tuberculosis, and certainly not as a cure, but as a useful addition to other methods of treatment.

Dr. J. Clifford Hoyle (Cambridge) read a paper on the serum calcium in experimental tuberculosis. Changes in the calcium metabolism had long been recognised to be associated with tuberculosis, and earlier observers had maintained that "demineralisation" occurred during the disease. No sound evidence existed for the belief that decreased calcium retention took place in tuberculous infections, except possibly in the terminal stages. This fact could probably be explained as being due to infection with secondary organisms. To support this view he gave the results of some interesting experiments carried out on rabbits. He had observed a striking difference between the serum calcium estimations when intraperitoneal as opposed to subcutaneous inoculations of bovine tubercle bacilli had been made. In the former the disease became generalised without an ulcer at the inoculation site, and in these cases little change was observed in the serum calcium curves, but in the latter where an ulcer infected with secondary organisms formed, the serum calcium fell steadily. If the ulcer healed, as sometimes happened, the serum calcium rose again, even while the generalised disease became steadily worse. Septic infection in previously normal rabbits also produced a considerable fall in the serum calcium.

Dr. W. H. Tytler (Cardiff) gave the results of his work on the "tuberculin-active fraction of the tubercle bacillus." He referred at length to the work of previous observers, especially of Long and Siebert. His own work had been primarily concerned with the production of a highly active preparation for experimental work. His methods of preparation were, in principle, similar to those of other workers, and his product was not a newly discovered substance, but was a highly active fraction with some practical application. The substance, obtained by the method of which he gave full details, was non-dialysable, and consisted of protein with a small admixture of proteose. Then nitrogen content varied from 11 to 12·5 per cent. The active fraction used for skin reactions gave a more sharply defined reaction than tuberculin, particularly at low concentrations. It might be stored in dry form, was accurately

Dr. J. R. REES (London) said that there were comparatively few who realised that the moral disorders, the character and personality defects of childhood, were the forerunners of much of the mental disorder of later life. Psychology should be studied in the nursery and in the infant school, and the general practitioner was the ideal person to tackle this early period. He had the entrée to homes and the confidence of patients. He asked if the B.M.A. could not initiate a campaign of education. The mental hygiene movement in America did a vast and altogether admirable work which was practically left untouched in this country. The general practitioner, with his experience and balance, was well able to get hold of the essential facts that were known, and would in consequence be infinitely better equipped to deal with the earliest manifestations of trouble and to do preventive work of inestimable value. Clinics, early treatment centres, and child guidance centres must come, and it seemed to him essential that the profesion should have adequate knowledge if it was to coöperate adequately with these specialised institutions.

Dr. GOODALL (the President) said the delay in dealing with the recommendations of the Royal Commission on Mental Disorders in respect of facilities for early treatment was deplorable. He detailed the arrangements at Cardiff for dealing with early cases in an out-patient department of the Cardiff Royal Infirmary during the past seven or eight years. Dr. Goodall stated that the 30 to 40 per cent. of patients amongst the direct admission to the Cardiff Mental Hospital who were annually discharged within six months of admission could—the majority of them—be treated at a psychiatric clinic, quite apart from the lunacy laws as at present constituted, and all the drawbacks which those laws implied. His constant advice to the Cardiff Local Authority was to rigidly abstain from any addition to their mental hospital, and to concentrate upon provision, in conjunction with the Cardiff Infirmary, of a fully-equipped clinic in psychiatry.

Dr. DORIS ODLUM (London) desired to emphasise most strongly that the provision of a psychiatric out-patient department in association with a general hospital was most valuable, not only in the interests of patients, but also as a means of educating the public, nurses and doctors in other departments of the hospital. Adequate social service in connexion with such a department, and specially trained welfare workers were also essential.

Dr. W. A. POTTS (Birmingham) said that the two most important centres for early treatment to be carried out were: (1) the infant welfare clinic, which provided the earliest opportunity for the examination and training of the child; (2) the antenatal clinic, where the attitude of the mother, and also of the father, to life, and also to the child, might be investigated, and, if necessary, adjusted. It was necessary to correct any misunderstanding that might arise from what was said about the damage of a sentimental attitude towards delinquents, by saying that those who were engaged in work with delinquents were out for justice, and for an opportunity for developing and drawing out the diminished sense of responsibility many delinquents had.

Dr. R. S. ALLISON (Ruthin) referred to some physical aspects of the treatment of the psychoneuroses. From the physical standpoint the first essential after a careful history was a thorough physical examination, and following this, investigations along bacteriological, biochemical, and radiological lines. The object in making these investigations was twofold: (1) the search for toxic foci, (2) to ascertain the physical peculiarities of the patient. The teeth, the throat, the accessory sinuses of the nose, the appendix, the gall-bladder, the colon, the urine and fæces were commonly the sites of a latent infection. In many cases this might be only detected after a thorough investigation of the case.

Dr. C. FORBES (Aberdeen), speaking as a general practitioner, desired to support strongly Dr. Rees's suggestion regarding the education of the profession. The proposition should be urged by all who were interested in the early treatment of mental and nervous illness. There was a definite need for the institution of clinics as a medium not only of research and treatment, but also for the education of family doctors in the particular area served.

SECTION OF TUBERCULOSIS.

RELATION BETWEEN TRAUMA AND TUBERCULOSIS.

Mr. H. MORRISTON DAVIES (Ruthin) was in the chair, when Dr. NORMAN TATTERSALL (Leeds) read a paper on the relationship between trauma and tuberculosis from the physician's standpoint. He considered that inoculation tuberculosis, such as butchers' and pathologists' warts, and acute generalised miliary tuberculosis following such injuries as a blow on a tuberculous testis, forcible movement of a tuberculous joint, and operations on tuberculous glands came into the category of traumatic tuberculosis. In 300 cases of pulmonary tuberculosis he found six cases in which trauma was suggested as the exciting cause, and in four of these, very definite symptoms had bridged the gap between the injury and the onset of the pulmonary lesion. He regarded as satisfactory Parkes Weber's classification of such cases into (1) those in which no tuberculosis was suspected prior to the injury, and (2) those in which tuberculosis was known to exist before the accident. An injury rarely produced a state of lowered resistance to the implantation of tubercle bacilli, and the more probable explanation was that the injury had activated an existing focus of disease. To support this contention he instanced the work of Opie and others who had isolated tubercle bacilli from gland and lung tissue which showed no naked-eye evidence of tuberculosis. Further, accidental wounds in tuberculous patients healed readily. Although injury to the chest might give rise to any form of pulmonary tuberculosis, the disease did not necessarily start on the same side as the injury. Compression injuries were more potent in exciting pulmonary tuberculosis than penetrating wounds. The course of the disease subsequent to injury might be acute, subacute, or chronic. Such symptoms as pleurisy and hæmoptysis were of great importance in fixing the date of onset, but it was very important in the assessment of claims for compensation that "bridge" symptoms should be present between the injury and the diagnosis. He suggested the following questions as helpful in arriving at a decision.

1. Was the patient actively or passively tuberculous before the accident, and if the former, what was his expectation of life?
2. Is the fact of injury definitely established, and was it of such a nature as to be likely to damage an active or quiescent lung focus?
3. What period of time elapsed between the injury and the diagnosis, and was the period covered by bridge symptoms?
4. Is the present condition of the patient and the course of the disease such as might be expected if the injury had reawakened or aggravated an existing latent focus of disease?

Mr. ROBERT MILNE (London), in discussing the question from the surgeon's point of view, said that whereas trauma may lead to a wound and to the implantation of tubercle bacilli in the damaged tissues, weakness from unsuspected tuberculosis, as for example in the knee-joint, may also lead to an accident. In some cases trauma may give rise to an infection of the injured part with tubercle bacilli from the blood stream, but, in his opinion, the percentage of such cases usually given (30 per cent. according to some authors) was much too high. He would put it as low as 2 to 5 per cent. Modern diagnostic methods had shown that many of the so-called tuberculous lesions following trauma were culosis. In his opinion, the expenditure of time and money had not been justified. The mortality from tuberculosis in 1821 was 25 per cent., in 1871, 12 per cent. So that, at a time when no preventive measures had been taken, the mortality had fallen to half. Since then, with the advent of the campaign, the mortality had fallen only 3 per cent. He explained this as being due to the fact that tuberculosis was an epidemic disease and that, as in all epidemics, the virulence of the bacillus had been greatly attenuated until the disease was now very mild, and in fact endemic. In 50 years' time it might again become epidemic. Immunity in his opinion was inherited, and by way of illustration he cited his experience among negroes who had come to the East-end of London. In one half-caste family he had observed that the boys, who all had a touch of the "tar-brush," died from tuberculosis, whereas the girls, who had inherited mostly the characteristics of the white parent, were still alive. We should aim at producing a race immune from tuberculosis. Before people marry they should look into the family history as well as into the banking account.

Dr. R. CAMERON (Cardiff) said that early diagnosis was sometimes tragically simple, and in other cases exceedingly difficult. He pointed out that in Cardiff, during 1926, 527 fresh cases of tuberculosis had been notified and that the number of deaths from the disease was 288. These figures were relatively small, as during the year no serious influenza epidemic had occurred. After giving other interesting details as to the prevalence of the disease, and the housing conditions, together with the number of contacts, he proceeded to the detailed account of the early diagnosis of pulmonary tuberculosis, basing his description on Pottenger's classification of the symptoms into pulmonary, reflex, and catarrhal. He next emphasised the diversity of the modes of onset of pulmonary tuberculosis, and finally discussed the various methods of physical, laboratory, and radiographic examination. The tuberculin tests were not, he considered, of practical value to general practitioners.

Dr. J. R. GILLESPIE (Belfast) thought that the subcutaneous tuberculin test, but not Pirquet's skin reaction, was of great value in diagnosis. During the past 15 years he had found 300 cases giving negative results to the test, and of these only five subsequently developed tuberculosis. It should be remembered that a negative tuberculin test did not mean that the patient would be immune for life.

Dr. AMBROSE OWEN (Aberdare) agreed with Dr. Kennedy that tuberculosis was on the decline, but he thought that public health measures had done much to decrease the incidence of non-pulmonary tuberculosis. Epidemics of other diseases such as influenza were largely instrumental in increasing the incidence of pulmonary tuberculosis. Contrary to Dr. Kennedy's opinion, he found phthisis more acute than it was 15 years ago. Pleurisy and hæmoptysis were not always indicative of tuberculosis. Hæmoptysis especially was a frequent complication in epidemic influenza. A striking fact was that hæmoptysis occurred in phthisical and non-phthisical patients during the same seasons, and in the former was often due to secondary infections. Our failure to control the great epidemics affecting the respiratory system was one of the reasons why phthisis was still so rampant.

Dr. R. J. MATTHEWS (Newport) pointed out the contrast beyween tuberculin reactions in the urban and rural populations. The former gave positive and the latter negative reactions in most of the cases he had tested.

Dr. KENNEDY, in reply, said that we could only judge the results of treatment by statistics. Epidemics ceased owing to the attenuation of the germ and to the elimination of the susceptible people by death. By keeping alive those susceptible to tuberculosis, we were doing our own progeny a grave injustice.

EXHIBITION OF DRUGS, SURGICAL INSTRUMENTS, FOODS, AND APPLIANCES.

(Concluded from p. 302.)

SURGICAL AIDS; HOSPITAL AND LABORATORY EQUIPMENT.

[21] The Denver Chemical Manufacturing Co. and [25] The Thermogene Co., Ltd. (Haywards Heath, Sussex, and Victoria Embankment, E.C. 4), displayed their well-known "Antiphlogistine" and medicated wadding respectively for the few who are not already convinced of their value.—[53] Baird and Tatlock, London, Ltd. (14–15, Cross-street, Hatton-garden, E.C. 1), from a large selection of bacteriological, pathological, and physiological apparatus, selected for special attention an incubator with a patent registered regulator; Kahn's outfit for the precipitation test of leprosy and syphilis; and Horrock's outfit for detecting chemical poisons in water.—[79] British Distribution Co. (52, Mortimer-street, W. 1) demonstrated the "Camp" physiological supports, embodying certain patent adjustments designed to give correct anatomical support without undue constriction and with the required pressure and uplift. Special models shown were the "Camp" ptosis support for gastric or intestinal prolapse; "Camp" visceroptosis support, giving a flattening yet upward-cupping effect, and "Camp" post-operative supports.—[29] R. H. Dent (309, Oxford-street, W. 1) had devised several new features of the "Ardente Aid for the Deaf." The wrist-watch pattern, shown last year, has been followed by the "hat-button," which can be pinned inside the lining of a hat and is remarkably inconspicuous. The latest stethoscope is smaller than its predecessors, can be used monaurally or binaurally, and gives a very clear enhanced sound with complete absence of electrical noises.—[35] Fassett and Johnson, Ltd. (86, Clerkenwell-road, E.C. 1), were showing again the well-known Mead's rubber adhesive plaster, and Seabury's "Gold Cross" absorbent cotton, as well as plasters, ligatures, and bandages.—[85] General Acoustics, Ltd. (77, Wigmore-street, W. 1), drew special attention this year to the new "Dime" earpiece, about the size of a sixpence and weighing two ounces, worn without head-band or crook, and leaving the hands free. The midget battery is very powerful and gives no distortion.—[15] Theodore Hamblin, Ltd. (15, Wigmore-street, W.1), showed ophthalmic instruments and equipment, including the Lister-Morton luminous ophthalmoscope; a new children's astigmatic test by Mr. E. E. Maddox; the Lawson self-contained operating lamp for use where no electric current is available; and a special display of telescopic spectacles for operating and for low visual acuity.—[13] Charles Hearson and Co., Ltd. (68, Willow-walk, S.E. 1), showed a wide range of incubators, ovens, stills, centrifuges, and other laboratory equipment, including the "Hellige" comparator for estimating pH values; a new "Klett" top-reader colorimeter, and several new Reichert microscopes, especially a monobinocular one on a new principle. This firm has opened a new show-room at 27, Mortimer-street, W. 1.—[40] Hoskins and Sewell, Ltd. (Bordersley, Birmingham), emphasised the usefulness of the new patent castor-pad action for allowing the bedstead to stand firm on rubber pads or to be wheeled on castors. They also showed the Nottingham Children's Hospital wheeling cot; the S. P. Smith's extension fittings with side attachment for abductions, by which any and all fractured limbs can be fixed; and several other bed attachments and screens.—At Stand [56], The Inhaling Drug and Apparatus Co., Ltd. (30, Grosvenor-place, S.W. 1), we learned that even insulin may now be administered by inhalation therapy, while excellent reports have been received of the use of the Spiess-Drager drug nebulising and inhaling apparatus in the treatment of tuberculosis and whooping-cough, as well as asthma and other lung conditions.—[64] Short and Mason, Ltd. (Atlantic House, 45–50, Holborn-viaduct, E.C. 1), demonstrated

measurable by weighing, and was stronger than old tuberculin. He had no reason to believe that it would have any greater therapeutic value than tuberculins in general.

In the afternoon Mr. MORRISTON DAVIES and Mr. TUDOR EDWARDS gave a demonstration of the results of thoracic surgery, and later, at the Cardiff Royal Infirmary, showed a series of patients on whom thoracoplasty had been performed. Dr. PARRY MORGAN (Cardiff) showed his artificial pneumothorax apparatus fitted with a double manometer.

AFTER-EFFECTS OF SURGICAL PROCEDURES IN PULMONARY TUBERCULOSIS.

Mr. TUDOR EDWARDS (London) opened the discussion by reading a paper on the after-effects of surgical procedures in cases of pulmonary tuberculosis. He regarded the after-results as being due to a series of factors such as: (1) the right choice of cases, (2) the type and extent of the operation, (3) the anæsthetic employed, (4) the operative mortality and complications, and (5) the after-treatment. In discussing the choice of cases for operation, he said that the chief factor was the condition of the "better" lung, which should show no active disease for at least three months prior to the operation. In cases of doubt it was his custom to perform a preliminary phrenic evulsion on the more-affected side in order to test the capacity of the better lung to withstand the increased strain to be placed on it. In his experience there was a tendency to wait too long before the surgeon was called in. The chances of recovery by surgical measures diminished with the increase of the amount and activity of the disease in the lung. Surgical procedures in diseases of the chest had incurred a certain amount of unnecessary odium mainly on that account. Experience had convinced him that adequate collapse of the affected lung could be obtained by a preliminary phrenic evulsion and a subsequent two-stage thoracoplasty from the first to the tenth ribs posteriorly. In order to produce localised collapse, phrenic evulsion and pneumolysis were satisfactory operations. In tuberculosis, however, it was usually necessary to secure complete collapse. The best anæsthetic was a gas and oxygen combined with local anæsthesia. The operative mortality and the complications of thoracoplasty such as shock, pulmonary embolism, spread of disease in the opposite lung, and septic infection of the wound could be largely diminished by careful pre-operative and after-treatment. No complications had occurred in his cases of phrenic evulsion and apicolysis, nor had they required much in the way of after-treatment. In thoracoplasty, after-treatment is essential, an important feature being that the patient should spend from three to six months under sanatorium régime.

Dr. F. G. CHANDLER (London), in discussing the question from the physician's point of view, said that a physician, in recommending a serious operation, took a great vicarious burden on himself. He should ask himself the question, "Would I, if necessary, have this operation performed on a member of my family or on myself?" The surgeon's relationship to the patient was, in a sense, impersonal, and it was the physician who had to consider the operative risk, the possibility of after-pain and discomfort, and the ultimate result. In chest surgery there were peculiar difficulties. Problems of judgment arose as well as questions of technical skill. If it were possible, a combination of the physician-surgeon would be ideal, and there were indications that developments along these lines were taking place. The open operation for dividing pleural adhesions was, in his experience, usually followed by sepsis and empyema, although there was little disturbance from the actual operation. In phrenic evulsion the immediate risk was small, but some complications, such as hæmorrhage, hæmoptysis, air embolism, chylous fistula, pulmonary œdema, and injury to other nerves had been reported. He agreed with Morriston Davies that the operation was of undoubted value in basal tuberculosis and as an accessory operation in artificial pneumothorax. Apicolysis and pneumolysis were, from the physician's point of view, the operations of choice. The shock, after-discomfort, and operation mortality were negligible. A satisfactory packing substance had still to be found, but he was greatly interested in the possibilities of these operations. It was difficult to judge the merits of thoracoplasty, on account of the extremely variable results. The after-results could not be usefully discussed without a clear idea of the criteria of suitability and non-suitability. Of the cases suitable for the operation, he gave the following types: (1) If a successful artificial pneumothroax had been allowed to terminate with a recurrence of symptoms and re-collapse was not possible; (2) if an artificial pneumothorax was imperatively indicated in a case of progressive unilateral disease, yet by reason of adhesions, it was not possible to induce one; (3) if chronic unilateral disease was present causing distressing symptoms. The cases not suitable included: (*a*) those in which there was a suspicion of active or progressive disease in the "better" lung; (*b*) those in which the general resistance was poor; (*c*) those with fibroid phthisis with every prospect of a reasonably healthy life; and (*d*) cases with amyloid disease or tuberculous ulceration of the intestines. The operative mortality varied between 5 and 12 per cent., the after-pain and distress were frequently considerable, but the results of the operation were, on the whole, good. Surprisingly little deformity was produced. The result could not be guaranteed, but in some cases there was a prospect of complete and permanent recovery which no other method of treatment could procure. Oleothorax, although our experience of it was limited, would probably be of great value in preventing obliterative pleurisy in artificial pneumothorax.

Dr. D. W. FENWICK JONES gave the results of 24 cases of thoracoplasty carried out at the North Wales Sanatorium. His general impression was, that while it was a desperate operation in advanced cases, it was a pity that cases of earlier disease were not selected for the treatment.—Dr. WALL said that the last stronghold of the physician had been taken by the surgeon, but he agreed that the results of chest surgery were good, and he looked forward to the establishment of the chest specialist who would be both a physician and a surgeon.—Dr. D. A. POWELL (Cardiff) remarked that we were at the beginning of an important operative era, in which specialism would be regional, and not divided into medicine and surgery. He was somewhat disappointed with the results of artificial pneumothorax, and hoped that those of thoracoplasty would be better.—Mr. MORRISTON DAVIES, in showing a series of photographs and radiograms of cases of thoracoplasty, pointed out in the photographs the negligible deformity as compared with radiograms of the same cases showing extensive collapse of the lung and the chest-wall. He regarded the one-stage operation as better than the two-stage, because the pulmonary collapse obtained was more complete, and also because the patient did not have to face the anxiety and shock of two serious operations. He pleaded for the establishment of operating theatres in sanatoria, and thought that in this respect the example of the Welsh Memorial Association might well be followed.

Mr. EDWARDS, in reply, said that after-pain was largely due to bad technique. An operative mortality of 12 per cent., taking everything into account, was not excessive.

TUBERCULOSIS AS SEEN BY THE GENERAL PRACTITIONER.

Dr. ANGUS KENNEDY (London), in opening the discussion, said there had been a surfeit of laudation about the success of the campaign against tuberculosis. In his opinion, the expenditure of time and money had not been justified. The mortality from tuberculosis in 1821 was 25 per cent., in 1871, 12 per cent. So that, at a time when no preventive measures had been taken, the mortality had fallen to half. Since then, with the advent of the campaign, the mortality had fallen only 3 per cent. He explained this as being due to the fact that tuberculosis was an epidemic disease and that, as in all epidemics, the virulence of the bacillus had been greatly attenuated until the disease was now very mild, and in fact endemic. In 50 years' time it might again become epidemic. Immunity in his opinion was inherited, and by way of illustration he cited his experience among negroes who had come to the East-end of London. In one half-caste family he had observed that the boys, who all had a touch of the "tar-brush," died from tuberculosis, whereas the girls, who had inherited mostly the characteristics of the white parent, were still alive. We should aim at producing a race immune from tuberculosis. Before people marry they should look into the family history as well as into the banking account.

Dr. R. CAMERON (Cardiff) said that early diagnosis was sometimes tragically simple, and in other cases exceedingly difficult. He pointed out that in Cardiff, during 1926, 527 fresh cases of tuberculosis had been notified and that the number of deaths from the disease was 288. These figures were relatively small, as during the year no serious influenza epidemic had occurred. After giving other interesting details as to the prevalence of the disease, and the housing conditions, together with the number of contacts, he proceeded to the detailed account of the early diagnosis of pulmonary tuberculosis, basing his description on Pottenger's classification of the symptoms into pulmonary, reflex, and catarrhal. He next emphasised the diversity of the modes of onset of pulmonary tuberculosis, and finally discussed the various methods of physical, laboratory, and radiographic examination. The tuberculin tests were not, he considered, of practical value to general practitioners.

Dr. J. R. GILLESPIE (Belfast) thought that the subcutaneous tuberculin test, but not Pirquet's skin reaction, was of great value in diagnosis. During the past 15 years he had found 300 cases giving negative results to the test, and of these only five subsequently developed tuberculosis. It should be remembered that a negative tuberculin test did not mean that the patient would be immune for life.

Dr. AMBROSE OWEN (Aberdare) agreed with Dr. Kennedy that tuberculosis was on the decline, but he thought that public health measures had done much to decrease the incidence of non-pulmonary tuberculosis. Epidemics of other diseases such as influenza were largely instrumental in increasing the incidence of pulmonary tuberculosis. Contrary to Dr. Kennedy's opinion, he found phthisis more acute than it was 15 years ago. Pleurisy and hæmoptysis were not always indicative of tuberculosis. Hæmoptysis especially was a frequent complication in epidemic influenza. A striking fact was that hæmoptysis occurred in phthisical and non-phthisical patients during the same seasons, and in the former was often due to secondary infections. Our failure to control the great epidemics affecting the respiratory system was one of the reasons why phthisis was still so rampant.

Dr. R. J. MATTHEWS (Newport) pointed out the contrast beyween tuberculin reactions in the urban and rural populations. The former gave positive and the latter negative reactions in most of the cases he had tested.

Dr. KENNEDY, in reply, said that we could only judge the results of treatment by statistics. Epidemics ceased owing to the attenuation of the germ and to the elimination of the susceptible people by death. By keeping alive those susceptible to tuberculosis, we were doing our own progeny a grave injustice.

EXHIBITION OF DRUGS, SURGICAL INSTRUMENTS, FOODS, AND APPLIANCES.

(*Concluded from p. 302.*)

SURGICAL AIDS; HOSPITAL AND LABORATORY EQUIPMENT.

[21] The Denver Chemical Manufacturing Co. and [25] The Thermogene Co., Ltd. (Haywards Heath, Sussex, and Victoria Embankment, E.C. 4), displayed their well-known "Antiphlogistine" and medicated wadding respectively for the few who are not already convinced of their value.—[53] Baird and Tatlock, London, Ltd. (14–15, Cross-street, Hatton-garden, E.C. 1), from a large selection of bacteriological, pathological, and physiological apparatus, selected for special attention an incubator with a patent registered regulator; Kahn's outfit for the precipitation test of leprosy and syphilis; and Horrock's outfit for detecting chemical poisons in water.—[79] British Distribution Co. (52, Mortimer-street, W. 1) demonstrated the "Camp" physiological supports, embodying certain patent adjustments designed to give correct anatomical support without undue constriction and with the required pressure and uplift. Special models shown were the "Camp" ptosis support for gastric or intestinal prolapse; "Camp" visceroptosis support, giving a flattening yet upward-cupping effect, and "Camp" post-operative supports.—[29] R. H. Dent (309, Oxford-street, W. 1) had devised several new features of the "Ardente Aid for the Deaf." The wrist-watch pattern, shown last year, has been followed by the "hat-button," which can be pinned inside the lining of a hat and is remarkably inconspicuous. The latest stethoscope is smaller than its predecessors, can be used monaurally or binaurally, and gives a very clear enhanced sound with complete absence of electrical noises.—[35] Fassett and Johnson, Ltd. (86, Clerkenwell-road, E.C. 1), were showing again the well-known Mead's rubber adhesive plaster, and Seabury's "Gold Cross" absorbent cotton, as well as plasters, ligatures, and bandages.—[85] General Acoustics, Ltd. (77, Wigmore-street, W. 1), drew special attention this year to the new "Dime" ear-piece, about the size of a sixpence and weighing two ounces, worn without head-band or crook, and leaving the hands free. The midget battery is very powerful and gives no distortion.—[15] Theodore Hamblin, Ltd. (15, Wigmore-street, W.1), showed ophthalmic instruments and equipment, including the Lister-Morton luminous ophthalmoscope; a new children's astigmatic test by Mr. E. E. Maddox; the Lawson self-contained operating lamp for use where no electric current is available; and a special display of telescopic spectacles for operating and for low visual acuity.—[13] Charles Hearson and Co., Ltd. (68, Willow-walk, S.E. 1), showed a wide range of incubators, ovens, stills, centrifuges, and other laboratory equipment, including the "Hellige" comparator for estimating pH values; a new "Klett" top-reader colorimeter, and several new Reichert microscopes, especially a monobinocular one on a new principle. This firm has opened a new show-room at 27, Mortimer-street, W. 1.—[40] Hoskins and Sewell, Ltd. (Bordersley, Birmingham), emphasised the usefulness of the new patent castor-pad action for allowing the bedstead to stand firm on rubber pads or to be wheeled on castors. They also showed the Nottingham Children's Hospital wheeling cot; the S. P. Smith's extension fittings with side attachment for abductions, by which any and all fractured limbs can be fixed; and several other bed attachments and screens.—At Stand [56], The Inhaling Drug and Apparatus Co., Ltd. (30, Grosvenor-place, S.W. 1), we learned that even insulin may now be administered by inhalation therapy, while excellent reports have been received of the use of the Spiess-Drager drug nebulising and inhaling apparatus in the treatment of tuberculosis and whooping-cough, as well as asthma and other lung conditions.—[64] Short and Mason, Ltd. (Atlantic House, 45–50, Holborn-viaduct, E.C. 1), demonstrated

the familiar "Tycos" sphygmomanometers, thermometers, and barometers. The new automatic recording type will be on the market shortly.—[92] Simco, Ltd. (22–28, Shand-street, S.E. 1), showed a range of beds which contain no cast iron, and are, therefore, unbreakable, especially an adjustable fabric-bottomed bed in which the patient can be put into any position with a minimum of effort. The universal bottom can be fitted on any ordinary bed frame, and is, therefore, extremely convenient for home nursing.—[4] Spencer Corsets, Ltd. (Banbury, Oxon), stressed the fact that each garment made by them is designed for each individual patient from exact measurements by a trained corsetière. They drew particular attention to their sacro-iliac corset and abdominal supporting corset for visceroptosis and pregnancy.—[48] John Weiss and Son, Ltd. (287, Oxford-street, W. 1), had a display of surgical instruments, including many new models and modifications, and a great number in stainless steel. The display included thyroid and cystoscopic instruments, and Bishop Harman's scotograph.—[90] Whitfield's Bedsteads, Ltd. (109–125, Watery-lane, Bordersley, Birmingham), showed improved "Lawson Tait" fracture, epileptic, cardiac, and obstetric bedsteads, drawing attention to the fact that the double wheeling foot-end can be let down on to wood blocks when the bed is wanted steady. The obstetric pattern has nickel-plated crutches and a winding-up frame.

X RAY, LIGHT, AND HEAT APPARATUS.

[78] The Dowsing Radiant Heat Co., Ltd. (91–93, Baker-street, W. 1), showed samples of many modern appliances for the application of the Dowsing treatment, ultra-violet lamps, and electric radiators of all kinds, particularly an expanding radiant heat apparatus which can be used for both legs or the abdomen or a single limb.—[91] Philips Lamps, Ltd. (145, Charing Cross-road, W.C. 2), introduced the "Metalix-Portable," a new compact apparatus for the general practitioner, which packs into a suit-case, stands on adjustable telescopic legs, plugs into any wall fixture, and is absolutely shock-proof. There was also a new deep therapy tube for operation at 220,000 volts.—[77] The Solus Electrical Co. (100, Judd-street, W.C. 1) showed a 30-M.A. X ray transformer set, complete with all-metal control table; the Solus-Jarhns Potter-Bucky motor-driven revolving grid, with special centring device; the valve-rectified "Solustat" apparatus; an air-cooled double-gap diathermy apparatus, and a great range of electro-medical and ultra-violet apparatus.

BOOKS.

[5] Messrs. Baillière, Tindall and Cox (8, Henrietta-street, W.C. 2) exhibited English and American medical and scientific books from their own press, as well as those issued by a number of other firms.—[68] Messrs. J. and A. Churchill (40, Gloucester-place, W. 1) showed an interesting series of medical directories, from the small crown octavo of an inch thick, of 1846, up to the enormous eighty-fourth issue of last year. Among other books were Massie's "Surgical Anatomy"; the seventh edition of Rowlands and Turner's "Operations of Surgery"; the new Taylor's "Medical Jurisprudence"; the ninth edition of Cushny's "Pharmacology"; and the "Recent Advances" series, of which the latest are: "Diseases of Children," by W. J. Pearson and W. G. Wyllie; "Surgery," by W. Heneage Ogilvie; and "Tropical Medicine," by Sir Leonard Rogers—[72] William Heinemann, Ltd. (99, Great Russell-street, W.C. 1), included in their exhibit MacCormac's new edition of Jacobi's "Atlas of Dermochromes"; the second edition of Dan McKenzie's "Diseases of the Throat, Nose and Ear"; McDonagh's "Nature of Disease"; and Halls-Dally's "Low Blood Pressure."—[37] H. K. Lewis and Co., Ltd. (136 and 140, Gower-street, W. 1), had a number of convenient clerical aids for the practitioner, including a new roll-top cabinet for panel envelopes in one. two, three, or four sections, each holding 500; and a useful series of instruction slips for patients, giving printed details, for instance, of how to prepare a fomentation, exercises for constipation, after-care of dental extractions, and alkaline treatment of gastric ulcer. On the covers supplied for these slips are relevant reminders for the doctor. Among the books recently issued by this firm are "The Injection Treatment of Varicose Veins," by A. H. Douthwaite, third edition; "A Shorter Anatomy" and "Anatomy for Artists," by E. Wolff; and "The Brain from Ape to Man," by Dr. Tilney.—[89] The Oxford University Press (Falcon-square, E.C. 1) showed text-books, manuals, and other works, including "Gastro-Intestinal Diseases," from the James Mackenzie Institute; the Robert Jones birthday volume; the fourth edition of Humphris' "Artificial Sunlight"; and the second enlarged edition of Fairbairn's "Gynæcology with Obstetrics."—[16] John Wright and Sons, Ltd. (Bristol), showed a large selection of books, including a new edition of Herbert French's "Index of Differential Diagnosis of Main Symptoms"; H. L. Tidy's "Index of Symptomatology"; C. P. Wakeley's and St. J. D. Buxton's "Surgical Pathology"; and the "Synopsis" series.

SPAS.

[94] Braceborough Spa (Lincs.) is already known as valuable for skin affections, and its water is now being prescribed for the treatment of latent infections. The calcium content is very high: 30·39 grs. per gallon of calcium bicarbonate, and is, therefore, recommended for all forms of calcium deficiency, particularly in infants.—[18] Harrogate (Baths and Wells Department) has added to its already diverse waters "Fango," a curative mud which has recently been discovered near the axis of the anticline around which the peculiar geological formation of the Harrogate strata centres. The mud is radioactive, and contains sulphur.—[3] The Stanboroughs is the London hydropathic establishment, and has excellent facilities for convalescent care and modern methods of treatment.

MISCELLANEOUS.

[74] The Food Education Society (29, Gordon-square, W.C. 1) displayed its dietetic books and pamphlets, including a number of Welsh editions. The latest leaflet, entitled "A Salad a Day," gives arguments and prescriptions for salads. Mr. Hecht's "School and University Diet" and "The Diet of Brain Workers" were selling well, and another useful publication on show was "The Reform of Institutional Housekeeping."—[86] The Hammond Varityper Co., Ltd. (75, Queen Victoria-street, E.C. 4), naturally laid emphasis on the special medical keyboards for typing prescriptions, and also the mathematical and chemical formulæ keyboards and those especially adapted for writing in foreign languages.—[36] The Medical Insurance Agency (B.M.A. House, W.C. 1) again recommended its valuable services, particularly drawing attention to the charitable work it is able to support both at Epsom College and for the orphan daughters of medical men. Messrs. Mann, Egerton and Co., Ltd., continue to act as consulting motor engineers to the agency.—[55] The Medical Sickness Annuity and Life Assurance Society, Ltd. (300, High Holborn, W.C. 1), offered its usual attractive policies to doctors and dentists.—[88] An unusual but very interesting exhibit was that of the Pentecon High-pressure Casserole Cooker, shown by Phillips and Proctor, Ltd. (125, High Holborn, W.C.1). In this simple covered saucepan food is cooked under a pressure of 45 pounds to the square inch. In this way the heat is greatly intensified, and any food can be cooked in eight minutes. It is almost impossible to overcook, and therefore a joint and vegetables can be put in together, the pressure adjusted by a simple device on the cover, and when the whistle blows a few minutes later all the contents will be found equally cooked. In addition to the obvious domestic advantage in saving time, worry, and fuel, there is a dietetic advantage in that the starch-cells are merely swollen and not burst by this cooking and the "goodness" is therefore conserved. The taste is certainly

excellent.—[66] Radiation, Ltd. (15, Grosvenor-place, S.W. 1), showed an exhibit of gas-heated appliances for dentists, and described by means of diagrams a series of experiments undertaken in an attempt to improve the quality of the heat emitted by gas-grates and cookers by obtaining a softer and more penetrating wave-length.—[75] The "Vita" Glass Marketing Board (Aldwych House, W.C. 2) attended for the first time to explain the properties and methods of fitting "Vita" glass which, while transmitting a large proportion of the ultra-violet spectrum, is indistinguishable from it in appearance, can be obtained from local builders, and is entirely British.

CONGRESS OF RADIOLOGY.

STOCKHOLM: JULY 23RD–27TH, 1928.

THE Second International Congress of Radiology which met in Stockholm from July 23rd to 27th, under the presidency of Prof. GOSTA FORSSELL (Stockholm), was attended by 962 members from 40 countries. T.R.H. the Crown Prince and Prince Charles of Sweden were present at the inaugural meeting in the Concert House, when Prof. Forssell received the presidential badge, a gift from the British Institute of Radiology, at the hands of Mr. C. Thurstan Holland and Dr. Stanley Melville, respectively president and secretary-general of the First International Congress held in London in 1925. The President then opened a discussion on Teaching and Training in Medical Radiology, expressing his own conviction that radiology has become so important to medical science as a whole, and so firmly established as a department of that science, as to make a systematic presentation of the subject an essential part of the general medical education. He was followed by Dr. J. BELOT, speaking for France, Prof. M. HICKEY, for U.S.A., Dr. G. HOLZKNECHT, for Austria, Dr. MELVILLE, for Great Britain, and others, all whose papers will be published in book form as a supplement to *Acta Radiologica*. The sectional proceedings of the Congress took place in the Riksdagshuset, being divided into (1) Rontgen Diagnostics, (2) Rontgen and Radium Therapy, (3) Radiobiology and Heliotherapy, and (4) Radiophysics and Medical Radiology. Altogether 225 papers were read, one of which we published in our issue of August 4th (p. 221); abstracts of several others follow. In the first section a number of papers dealt with opaque injections into brain and spinal column for the diagnosis of tumours and other diseased conditions of the central nervous system (encephalography and myelography), into female genital organs (hysterosalpingography), into kidneys (pyelography and pneumopyelography), as well as the use of contrast means in the examination of the accessory sinuses of the nose. In the second section the chief interest centred around the radium treatment of malignant tumours and the X ray treatment of nervous disease of different kinds—tuberculosis, goitre, and diseases of the skin. The organisation and the results obtained at Radiumhemmet in Stockholm were illustrated by a demonstration of some 100 patients. In the third section papers were read on the effect of light in various diseases, the action of ultra-violet rays on cells and tissues, and the therapeutic value of irradiated oils. The fourth section had two main themes on its programme: (1) the establishment of an international unit of dosage in X ray treatment, to which a leading article was devoted in our columns last week; and (2) the question how to obtain international regulations for protection in radiological work. The latter led to the setting up of an international committee to carry out with a few small alterations the recommendations of the British X ray and Radium Protection Committee. During the Congress the International Committee of Radiology met and appointed an executive committee consisting of Prof. Forssell, Mr. Thurstan Holland, Dr. A. Béclère, Prof. W. Friedrich, Prof. M. Haudek, Dr. G. A. Pfahler, and Prof. P. Tandoja, which fixed Paris as the place for the Third International Congress in 1931, with Dr. Béclère as its president. An exhibition in connexion with the Congress comprised apparatus shown by 45 firms, of which 24 were from Germany, 7 from England, and 5 from Sweden.

Rationale of Radiation Therapy.

Invited to contribute a paper on this subject Dr. ROBERT KNOX (London) dealt with the radiation treatment of certain diseases, arranged for convenience of reference in groups. In the cases treated, at one period or another, a degree of control was obtained by systematic dosage; to ascertain the nature of this control innumerable observations were made in regard to dosage, absorption of the radiations, and the nature of the response of the tissues to these radiations. Two main fields of investigation were open: (1) the physical dose, and (2) the tissue response. It was decided to concentrate on one tissue and, because of the advantages offered by the blood, it was arranged, as a preliminary investigation, to explore the changes induced in blood and bone marrow by X rays of known wave-length. Mr. W. V. Mayneord made the precise physical measurements of the radiation. The tissue response was measured by Dr. A. Piney, who observed the hæmatological and histological changes in a number of animals subjected to measured doses of X rays. The direction of the experimental work was suggested by the clinical observations made in a case of myelogenous leukæmia where apparently a progressive action on the blood was induced by measured doses of radiations, and where after cessation of treatment, changes, quantitative and qualitative, continued for several months until a minimum count was reached. The animal experiments establish that radiations initiate a change which is progressive, and which continues after the cessation of treatment, and independently of subsequent procedures. The conclusions are to some extent analogous to those made by Dr. A. Leitch on the production of cancer in animals by repeated applications of tar products; when the tar had been applied frequently and for a certain length of time and the irritant was then removed, carcinomata made their appearance at a later date. Dr. Piney found the effects of divided doses to be more intense and more prolonged than those of a single dose, whilst also having a rather different qualitative result—namely, the former cause no alteration in the monocyte count.

Massive Collapse of the Lung.

Dr. L. R. SANTE (St. Louis, Mo.) and Dr. D. R. BOWEN (Philadelphia) both read papers on this peculiar condition in which one or more lobes of the lung, without apparent cause, suddenly lose their air content and become atelectatic. First described by W. Pasteur in 1890, the condition is scantily mentioned in the literature until recent years. With the loss of air content the lung becomes smaller, drawing the chest wall down with it, the mediastinal structures inward and the diaphragm upward as it collapses. The resulting atelectatic lung produces as dense a consolidation as pneumonia. These rontgenographic findings are characteristic. Dr. Sante has observed under direct fluoroscopic vision that such a fully collapsed lung can be caused to reinflate in many instances, merely by rolling the patient back and forth on his unaffected side and causing him to cough, and he suggests this as a method of treatment. Dr. Bowen emphasised the recent rediscovery of atelectasis as a post-operative complication with precisely similar conditions to those recurring with foreign body or infectious disease.

Radium Treatment of Intrinsic Carcinoma of the Larynx.

Dr. N. S. FINZI and Mr. DOUGLAS HARMER (London) described their method as closely resembling that employed at Bayet's Clinic. The incision starts at the centre of the hyoid bone and extends outwards and downwards along the posterior border of the thyroid cartilage. The thyroid cartilage is exposed, the perichondrium stripped from it and the greater portion of the cartilage then resected, making a large window. A number of radium needles are then inserted under the cartilage, great care being taken not to penetrate into the growth or into the larynx. The needles are parallel and are placed vertically, each one touching the next. The greatest care is taken to prevent sepsis. The threads attached to the needles are buried beneath the muscles and the wound is completely closed until the needles are removed from 4½ to 8 days later. If the anterior commissure is involved the other side of the larynx is treated in the same way. About 7 mg. of radium element is used if one side only is treated and about 12 mg. if both sides are treated. The filter is 0·5 mm. of platinum and the time from 4½ to 8 days. In some cases a small dose of heavily filtered X rays has been given *two or three* days before the operation. The closed wound having been sealed by a collodion dressing, a low tracheotomy is performed to avoid trouble from swelling of *the glottis, which may result from the radium treatment*; this tracheotomy is usually kept open for about six weeks. Fifteen cases have been treated with the following result:—

(1) In eight of these the growth was confined to one vocal cord and did not involve either the anterior commissure or the arytenoid cartilage. In six the growths entirely disappeared and the patients have remained well for periods of from one to three years. Gramophone records will be used to show the superiority of the results as regards function over those obtained by laryngo-fissure. In most of them the vocal cords have recovered to such an extent that it is impossible to detect on which side the growths were situated. In one case the growth diminished in size, but a stenosis of the glottis resulted and the patient died suddenly eight months later of unknown cause. In the eighth case no real improvement resulted from the treatment.

(2) Five cases were advanced, the disease having crossed the middle line in front and involved the other vocal cord, so that nothing except some form of laryngectomy was available as a surgical procedure. One has remained well *for four years; his vocal cords are freely movable and* appear normal, but the voice result is not as good as would be expected (gramophone record). In one case the disease in the larynx entirely disappeared, but the patient died later from a recurrence, which occurred in the tracheotomy wound a year after the treatment. Of the other three cases, one died during the operation, in one no improvement was noticed, and in one there was improvement, but later recurrence.

(3) Two inoperable cases in which the disease had extended into the larynx or through the laryngeal cartilages into the neck with enlargement of the cervical glands. In one the growth disappeared and the glands were removed by operation; the larynx remained healthy for two and a half years, but there is now a thickening of the vocal cord, probably due to a recurrence. In the other there was very great improvement, but the patient died after 15 months, probably from mediastinal metastases.

It is claimed that in operable cases the after-results as regards function are superior to surgical operation, and, if they prove to be permanent, will probably replace it. In advanced cases there seems no doubt, they say, that radium should always be tried before laryngectomy.

X Ray Therapy of Exophthalmic Goitre.

Dr. G. FORSSELL and Dr. O. SANDSTRÖM (Stockholm) gave a survey of experiences at Radiumhemmet of the X ray treatment during the period 1918–25 of 80 cases of typical morbus basedowii. In 57 cases the treatment was completed and the results controlled by re-examination of the patients. Of these 57 cases 30 (52·6 per cent.) are now quite well and able to work; 13 (22·8 per cent.) are much improved and able to work, but still have certain symptoms; 75·4 per cent., therefore, have been rendered able to work; 5 cases (8·8 per cent.) are improved, but not quite able to work, and as many (5) are unimproved or worse; there are 3 (5·3 per cent.) recurrences after recovery or considerable improvement having lasted for some time; there has been one death. Approximately one-fourth of the number of cases have been of severe nature, the rest of medium severity. The risk of rontgen treatment in expert hands is slight. Yet there is a certain risk of producing hypothyroidism, particularly in case of the nutrition of the thyroid being reduced by some operative interference preceding or following the X ray treatment.

Dr. A. SOILAND, Dr. W. E. COSTOLOW, and Dr. O. N. MELAND (Los Angeles) gave a critical survey of radiation therapy in exophthalmic goitre, as revealed by a questionnaire, and show that of 5400 cases treated *73 per cent. were cured, 16 per cent.* improved, and 11 per cent. unimproved. Failures to respond to the treatment are attributed to poor selection of cases on the part of the physician, lack of coöperation on the part of the patient, and lack of radio-sensitivity of the goitre. Whether or not this last cause is correct cannot be definitely decided at present, as improvement in technique may eliminate it. This analysis gives figures which are comparable to those obtained in surgery, with the added advantage of no mortality due to the treatment itself.

X Ray Treatment of Multiple Sclerosis.

Stimulated by the published successes of Marinesco (1910) and Duhain (1911), Dr. A. Romanowa-Leskowa and Dr. K. W. Ipatow (Leningrad) began the treatment of *sclérose en plaques* by X rays in 1922, and reported good results in two cases at the Psycho-Neurological Society of Leningrad in 1924, and in a total of 30 cases at the Physiotherapeutic Society of Leningrad in 1927. Their cases now number 40, of which only 28 have been observed for more than a year; the remaining 12 were lost sight of after some improvement had been achieved. Treatment is administered in seven sittings; at intervals of 1–2 days the skull is irradiated three times, the neck once, the chest twice, and the sacrum once. This series is given ten times in the year, the whole course being repeated after an interval of 6 to 12 months. Of the 28 patients, 22 showed more or less definite improvement up to clinical cure, including improvement of *gait and speech, disappearance* of tremor, return of abdominal reflexes, and so forth. No case was completely unsuccessful, but six were only slightly bettered. Improvement may only be apparent after several months or even years. The authors employed hard rays filtered through 4 mm. of aluminium, and a dose not exceeding 25 per cent. HED measured on the skin.

New Method of Treating Asthma by Radiation.

While working on a special technique for treating cancer by radiation at the London Hospital, Dr. S. G. SCOTT noticed that the method had a *beneficial* effect on asthmatical patients. A number of cases of asthma of all types have now been treated; in really bad cases the results are often spectacular. When bronchitis is predominant, while the attacks of *asthma* may be relieved, the bronchitis itself is but little affected. Certain observations suggest some metabolic influence on the ductless glands—e.g., (1) beneficial results can be obtained by radiation of *the abdomen* only; (2) increase in body weight is in many cases remarkable; (3) there is a general feeling of well-being experienced by most patients. The method requires a large radiation field and small dosage. The field includes the whole trunk, the abdomen being the important area. The tubes are centred over the epigastrium and over a corresponding point posteriorly. The voltage should not be above *170,000*, a filter of 3 mm. aluminium being used. Treatment is given twice weekly in bad cases and once weekly in average cases, four to six being the course. No blood changes occur and only slight nausea in a *few* patients. Dr. Scott reported on 130 cases so treated, and suggested that the same technique might prove of value is whooping-cough.

Treatment by Irradiated Oils.

At the instigation of Prof. S. A. Brustein, Dr. Th. Rothstein (Leningrad) began three years ago to employ external treatment of painful affections by means of compresses of irradiated oil. The technique consists in exposing the fresh oil, whether obtained from the sunflower, peach, nut, or cod liver, to 500, 1000, or 1500 ultra-violet units measured on the Salkindson photo-quantimeter. The 176 cases treated included polyarthritis 71, neuralgia 92, the most conspicuous result being in every case a reduction of painfulness and a parallel diminution of local heat. The compresses seem to the author to have their use in every case where direct ultra-violet treatment is used, with the added advantage of portability. The activity of the irradiated oils lasts at least 15 months, during which time the oils retain definite physical and chemical changes in viscosity, absorption spectrum, and iodine number.

MEDICINE AND THE LAW.

Chemist's Duty under Dangerous Drugs Legislation: Conviction Quashed.

UNDER the Dangerous Drugs Act and Regulations a chemist must not dispense a prescription containing certain drugs unless (*a*) he is acquainted with the prescriber's signature and has no reason to doubt the genuineness of the prescription, or (*b*) he has taken reasonably sufficient steps to satisfy himself that the prescription is genuine. If he dispenses prescriptions otherwise than in accordance with the Regulations, he commits an offence against the Act. For an offence of this nature Henry Clarence Thompson, a chemist, of West Derby-road, Liverpool, was convicted last June by the Liverpool Stipendiary Magistrate, and was fined £40 with £5 5s. costs. The charge was that of unlawfully dispensing a prescription for grs. 20 morphia sulphate to William Arthur Young without having taken reasonably sufficient steps to satisfy himself that the prescription was genuine. Against this conviction Mr. Thompson has now successfully appealed. It appeared from statements made during the proceedings that Young had posed as a doctor in Liverpool without possessing the requisite qualifications, that he had attended patients and had even certified a mental case. Young was convicted of wilfully and falsely pretending to be a doctor and also of obtaining certain quantities of morphia sulphate from two chemists; he was sentenced to imprisonment, which he is at present serving. It was stated that he had practised as a doctor in Canada but had got into trouble, and lost his qualifications and had been deported. The prosecution of Mr. Thompson was obviously a sequel to the prosecution of Young. The most important evidence called on Mr. Thompson's behalf was that of Dr. W. R. L. Waters, of Tue Brook, who had met Young. Young told Dr. Waters that he was a Canadian mental specialist who wished to set up practice in Liverpool. "I did not look him up in the Register," said Dr. Waters; "he was a convincing person and had a good knowledge of mental cases; he impressed me as a man of ability, and I was satisfied that he was a medical man; I allowed him to see one of my patients with me, and he wrote out a detailed history of the case—a mental one." In answer to the Recorder (Mr. Hemmerde, K.C.), Dr. Waters agreed that the more a chemist had examined Young, the more he would have been satisfied that Young was a doctor; he also said that he would not have hesitated to let Young look after his patients at a week-end if he had been going away. The Recorder said that if there was nothing to make Dr. Waters suspicious, there was nothing to make Mr. Thompson suspicious. The latter's appeal was allowed with costs.

One medical practitioner meeting another occasionally in the course of professional routine does not hold him at arm's length till he has obtained authentic evidence of his identity, qualifications, and registration. Similarly a chemist, who gradually becomes acquainted with the signatures of doctors who practise in his neighbourhood, can hardly be expected to go through a similar process when presented with a prescription over a signature with which he is unfamiliar. Is it to be deemed compulsory for a chemist to keep on his premises a copy of the latest medical list? If he does so, he may still be deceived by a forged signature, or conceivably the owner of the signature may have been deprived of his qualifications since the list was published. Nevertheless, the law requires that such reasonably sufficient steps be taken by the chemist as will satisfy him of the genuineness of the prescription; he must certainly not refrain from following up any point which arouses his suspicion. With regard to Dr. Waters's answers to the Recorder, it is doubtless unnecessary to repeat the warnings which appear in "The Conduct of Medical Practice." A practitioner who enters into partnership, or who engages the services of an assistant, must in every case verify the fact of registration. Dr. Waters would no doubt have taken this step before entrusting any of his patients, for however short a time, to Young.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Medical Research.

Sir Robert Philip's report, as curator of the laboratory of the Royal College of Physicians of Edinburgh, shows that the 24 investigators there have been doing good work on many different subjects. The use of taurine in tuberculosis has been further studied, and its influence on the disease has been found to be comparatively slight. The curator, with Prof. T. J. Mackie, has been doing research bearing on the standardisation of tuberculin; the superintendent (Lieut.-Colonel A. G. McKendrick) and Dr. W. O. Kermack have been carrying on their work on the mathematical theory of contagious epidemics, and Colonel McKendrick has also published a statistical examination of antirabic treatment in India. He has further collaborated with Dr. Kermack and Dr. Eric Ponder in their research on the sedimentation of red blood cells, whilst Dr. Kermack has, with various collaborators, investigated the chemistry of harmine and other alkaloids, the rôle of dihydroxyacetone in carbohydrate metabolism, and the physical properties of Wassermann antigens. Mr. C. I. B. Voge has continued his studies of the reactions of syphilitic and normal sera; Dr. C. G. Lambie and Dr. F. A. Redhead have made some interesting observations on the influence of pituitrin on the metabolism of glucose and dihydroxyacetone; Dr. David Orr has investigated the changes to be found in the nervous system of animals receiving intravenous injections of bacterial emulsions, and Dr. Donald Stewart has carried to a further stage his work on the chemistry and cytology of the cerebro-spinal fluid in children. Lieut.-Colonel W. F. Harvey, a newcomer to the laboratory, is examining Gram's method of staining unicellular organisms, and has found efficient substitutes for the alcohol, aniline oil or phenol constituents of the dye. He is also studying the parenteral introduction of foreign nerve material into rats. Other subjects being dealt with are the conditions which favour heat-stroke, the infection of children by pulmonary diseases, the pathology of deaf mutism, the histopathology of the skin, the types of tubercle bacilli found in surgical lesions, and the icterus index of serum in cases of jaundice.

Status of the Sanitary Inspector.

At the annual conference of the Sanitary Inspectors Association, held at Dunfermline, Dr. Frederick Dittmar, Chief Medical Officer of the Scottish Board of Health, pointed out that the days were gone when it was believed that a policeman or a plumber should occupy the position of sanitary inspector. Generally speaking, the sanitary inspector nowadays had to know something about buildings, building construction, meat inspection, and dairy work, so that he must be a man of fairly wide training. He should have a first-class school training, and ideally should occupy some position similar to that of the articled pupil in the engineering trade, who first had his theoretical training, and then had to go through the shops. Something in that line would have to be marked out for the sanitary inspector of the future, and Dr. Dittmar thought it by no means impracticable. The status of the sanitary inspector might then take care of itself.

Factory Work and Welfare.

The report of the Chief Inspector of Factories and Workshops shows that there were over 18,000 accidents in Scotland last year, of which 145 were fatal. The deaths of two men who had for many years been employed in the manufacture of sheep dip present puzzling features.

> The first man, who had been engaged in the manufacture of dip for over 30 years, died from chronic arsenical poisoning, bronchitis, and emphysema. The senior medical inspector (Dr. J. C. Bridge) remarks that in this case no lesion of the skin—a characteristic effect of arsenical poisoning—was observed, and as no autopsy was held, the association of arsenic with the cause of death remained obscure.
>
> Inquiry was made into a somewhat similar case affecting a man, aged 51, who had been employed for 29 years also in a sheep dip works, although since 1923 he had been removed from contact with arsenic. Dr. Bridge states that "on three separate occasions growths had been removed from the skin, and in this case the post-mortem examination revealed the presence of chronic bronchitis, which might have been due to the exposure to arsenic dust, but this was not clearly established. A full investigation of cases such as these is of undoubted value."

A firm engaged in the manufacture of sheep dip has installed baths, and has made the taking of them a condition of employment of all those in contact with arsenical compound. Although there was, it is stated, a little difficulty at the outset, this was easily overcome, and subsequently these baths were made available for other employees, male and female.

Continued progress in improvement of welfare conditions is reported. A large printing and publishing firm in Lanarkshire has taken advantage of the decision to construct an up-to-date factory on model lines to launch an ambitious and comprehensive scheme of welfare work. Embodied in the design of the factory itself is every modern improvement that makes for efficiency and general welfare. The site has been chosen in the country, but by reason of excellent and cheap travelling facilities, the city centre is not far distant. The kitchen is entirely electrical, and meals are to be provided for the workers at prices scarcely above cost, whilst, for those who prefer to bring their own food, specially designed warming cabinets are provided. The lavatories are described by the works manager as probably superior to those in the best hotels of the country, and a separate self-locking lavatory has been allotted to each group of 20 workers, every worker being provided with a key.

V.A.D. Road Services.

At the Voluntary Aid Detachment gathering at Aboyne, the proposal was discussed to utilise the services of V.A.D. nurses for first-aid and other work in connexion with road accidents. Dr. J. C. M. Matheson, of Laurencekirk, said that headquarters had expressed their approval of the scheme, and he was hopeful of seeing all arrangements in Kincardineshire completed shortly. War was a very remote possibility, and a vigorous effort should be made to deflect the training and experience of many capable nurses into the service indicated.

The movement is also receiving support in Aberdeen, and is expected to spread to other counties in Scotland.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Censorship of Publications.

IMMEDIATELY before the adjournment of the Dail the first reading was taken of the Censorship of Publications Bill, 1928, a measure designed to prohibit the sale and distribution of unwholesome literature. The text of the Bill has, however, been issued only within the past few days. Apart from its purely moral and social aspects the Bill has special interest for the medical profession. It is proposed to set up a board of five censors, on the report of four of whom the Minister of Justice may issue an order prohibiting the sale or distribution of a book regarded by them as indecent or obscene, or tending to inculcate principles contrary to public morality, or of such character that it tends to be injurious or detrimental to or subversive of public morality. Similar action may be taken in regard to a periodical, recent issues of which may be adjudged to have offended. Disobedience to an order may be punished by fine or imprisonment, or both, and, in any case, forfeiture of the book or periodical. Special sections limit the publication of certain matters in relation to divorce proceedings or other proceedings dealing with the marital relation, and legal proceedings in general. The Bill, however, goes much further than this. *It prohibits, otherwise than in accordance* with a permit granted by the Minister, the publication, selling, or keeping for sale, and the distribution of *any book or periodical* which *advocates* or might reasonably be supposed to advocate the unnatural prevention of conception or procurement of abortion *or miscarriage, or any method*, treatment, or appliance to be used for the purpose of such prevention or procurement. Moreover, the printing of advertisements which relate or refer to any disease affecting the generative organs of either sex, or to any complaint or infirmity arising from or relating to sexual intercourse, or to the prevention or removal of irregularities in menstruation, and certain other matters, is brought under the Indecent Advertisements Act of 1889. Another section deals with the exposure of indecent pictures.

Much of the proposed legislation deserves commendation. The prohibition of the advertisement of quack cures for venereal diseases and of "cures for female irregularities" is long overdue. Few will quarrel, except perhaps on academic grounds, with the limitation of the reporting of divorce and similar legal cases—a reform already adopted in England. But the virtual branding of propaganda in favour of birth control as indecent will take many aback. The ethics of birth control are a subject of lively controversy at the moment, and the ethical question can hardly be settled by a legislative enactment. *In regard to other* matters there is a grave danger that if a board of puritanical or uncultured censors should be appointed, both literature and art would *speedily* feel themselves cramped.

Royal Institute of Public Health.

The annual congress of the Royal Institute of Public Health was opened in Dublin last Tuesday evening by a reception given by the Minister of Local Government and Public Health, who is President of the Congress. On the following and subsequent days the several sections met for discussion.

A LANCASHIRE REST HOME.—The Directors of British Insulated Cables, Ltd., of *Prescot*, Lancashire, have bought Upper Downing, Flintshire, for a rest home as part of an after-care scheme for sickness and accident cases among their employees. The cost of *maintenance* will be defrayed by the Hospital Fund Committee of the employees. Upper Downing, which by now has been opened, was built in 1589, *but* was *remodelled* in the Georgian period. It stands close to Downing Hall, long the *home of Thomas* Pennant, traveller and naturalist.

GENERAL MEDICAL COUNCIL.

EXECUTIVE COMMITTEE.

AT a meeting of the Committee, held on July 23rd, Sir Norman Walker was appointed a member of the Dental Board in the place of the late Sir James Hodsdon.

Restorations to the Register under Section 14.

The following names, erased owing to failure to reply to the Registrar's inquiry, were restored to the Medical Register:—

Thomas Allen, Robert J. Baylor, Chas. Wm. Dixon, John Douglas, John Dwyer, Mervyn Eager, Lennard Game, Harold W. Hodgson, M.C., Elizabeth S. Martin, Vivian Matthew Matthews, Evelyn Arthur Rich.

Direct Representative.

A letter was read from Sir Robert Bolam, resigning his membership of the Council as a Direct Representative on his appointment as Representative of the University of Durham. The vacancy thus caused will be filled by an election to be held before the November Session, at the same time as the election of a Direct Representative to fill the vacancy caused by the death of Dr. Macdonald.

Union of South Africa Medical Act.

A copy of this Act, which also relates to the mandated territory of South-West Africa, was received from the Dominions Office. This Act provides that the Governor-General, after considering any recommendation by the Council, may prescribe by regulation the diplomas, &c., which entitle to registration provided that they entitle the holder to practise in the country in which the body granting it is situated, that there is reciprocity between the Union and the country, and that the standard is not lower than that required in the Union. The Governor-General may make regulations for the registration of medical and dental students. Any unregistered person who practises as a medical practitioner, or performs any act specially pertaining to the calling of a medical practitioner, or pretends to be a medical practitioner, is liable to a fine not exceeding £100. There are similar penalties provided in regard to dentistry. The use of the British Pharmacopœia is enjoined. No registered person may make extortionate charges for services rendered, and if the fee exceeds that usually charged he must, before rendering the service, inform the person concerned of the fee which it is intended to charge. Persons mentally disabled may be suspended from carrying on their profession.

North Australia.

Information was received from the Dominions Office relating to the practice of medicine and surgery in the Territory of North Australia. It appears that the South Australia Acts of 1844, 1880, and 1889 were in force in 1910 when the Northern Territory came under the authority of the Commonwealth, and still hold. The Act of 1844 states that no one shall be deemed a legally qualified medical practitioner unless he shall have proved to the satisfaction of the Medical Board that he held a satisfactory qualification. In the Act of 1880 this was repealed, and it was enacted that no one was to be deemed a medical practitioner unless he possessed one of the qualifications contained in the Schedule. The Schedule, however, was not supplied. In the Act of 1889 the Schedule was repealed, and a new Schedule was appended, which included any qualification entitling to registration in the United Kingdom, a degree of any University in Australasia legally authorised to grant it, and a degree or diploma granted by any body in a British Colony or Possession, or any foreign University which in the opinion of the Medical Board was equal to a qualification entitling to registration in the United Kingdom.

Indian Qualifications.

A communication from the India Office supported a request by the University of Bombay for the extension of the recognition of its M.B., B.S. degree of the University for a further period of three years. The question of appointing a Commissioner of Qualifications and Standards pending the creation of a Medical Council for India has, it was stated, been referred by the Government of India to the local Governments for their consideration. Their replies have not yet been received. It was resolved to recognise for one year the medical degrees of Bombay, Calcutta, Madras, and Punjab Universities, until July 31st, 1929, subject to the receipt (before July 1st, 1929) by the Council of a satisfactory report by an inspector or inspectors appointed by the Government of India and approved by the Council on a Final Examination held in the academic year, 1928–29.

Training of Midwives.

In view of the appointment by the Ministry of Health of a Committee to deal with the functions and training of midwives, it was resolved to ask Sir Donald MacAlister to attend before the Committee on Oct. 24th to explain the general views of the Council, and to introduce Mr. Eason, Sir Leslie Mackenzie, and Mr. Johnston, who should be requested to give evidence relating to the three divisions of the Kingdom.

Definition of Abortion.

At a previous meeting of the Committee, doubt was expressed as to whether the definition of "abortion" in the amended Rules of the Central Midwives Board was sufficiently clear or accurate. The Ministry of Health stated that the definition had been altered to read as follows:—

> "The passage of the contents of the uterus before the fœtus is viable—that is, of an age at which it may be reasonably expected to survive. (Note.—For practical purposes a fœtus is not viable before the twenty-eighth week of pregnancy.)"

Obituary.

GEORGE EDWARD WHERRY, M.CHIR. CAMB., F.R.C.S.ENG.

WE regret to announce the death of the well-known Cambridge surgeon, Mr. Wherry, which occurred on August 12th, in the seventy-seventh year of his age. The whole of his professional life was spent in the University city, and the number of Cambridge medical graduates who have regarded him as a friend, both during their undergraduate days and later, must be enormous.

George Edward Wherry was born at Bourne, in Lincolnshire, received his early education at the local grammar school, and, entering the medical school of St. Thomas's Hospital in 1870, obtained his first diploma, M.R.C.S.Eng., at the age of 21. From St. Thomas's Hospital he proceeded to Cambridge as house surgeon at Addenbrooke's Hospital, being admitted at the same time to Downing College as an undergraduate of the University. He held the resident post at Addenbrooke's for four years, and during that time graduated in arts at the University. He took the M.B., B.Ch. degree in 1878, and in the following year he proceeded to that of M.C. In the same year he took the Fellowship of the Royal College of Surgeons of England, and was appointed surgeon to Addenbrooke's Hospital.

In 1883 Sir George Humphry, to whom Wherry owed his original connexion with Addenbrooke's Hospital, resigned the Professorship of Anatomy to take the new and unpaid Professorship of Surgery, and in the same year a University Lectureship in Surgery was established, when Wherry was appointed to the post and held it until its suppression nearly thirty years later. He was never actually Professor of Surgery. This post was not filled up for seven years after Humphry's death in 1896, when in 1903 Howard Marsh, while still connected with St. Bartholomew's Hospital, was invited to the chair. Four years later Marsh became Master of Downing College, and held the post of Professor until his death, since which it has not been filled up. But if Wherry was never professor in name, no professor could possibly have been more closely associated with the science of surgery as a University subject or more keen for its development than he was. He lectured assiduously, held clinical classes in the wards, acted frequently as an examiner, and supervised during the ten years immediately following the death of Howard Marsh the whole surgical faculty of the University.

Outside his professional work Wherry was well-known to a large circle as an Alpine climber, an antiquarian, and a man of diverse and highly cultivated literary tastes. He married in 1881 Albinia Lucy, daughter of Robert Needham Cust, of the Bengal Civil Service, by whom he had one daughter, who became the wife of Major R. W. Oldfield, Military Attaché to the Legation at Prague.

CHRISTOPHER CHILDS, M.D.Oxf., D.P.H.Camb.

THE death took place on Monday, August 6th, at his residence, Rock House, West Looe, Cornwall, of Dr. Christopher Childs, a well-known pioneer in sanitation and epidemiology. He had reached the age of 81.

Christopher Childs was born at Liskeard, and received his early education at Uppingham School, where he was distinguished alike in work and play, being an exhibitioner, a great runner, and the captain of the football fifteen. From Uppingham he proceeded to Merton College, Oxford, and graduated with a first class in the Natural Science Tripos. Deciding to enter the medical profession, and having won the Radcliffe Trust Special Prize, he completed his clinical course at St. George's Hospital, took the diplomas of the English Colleges, and became house physician to the institution. London practice, however, had no great attraction for him, and for a short time he returned to his old school as science master, when he was able to assist the famous head, Edward Thring, during a dramatic transference of the school from Rutlandshire to Wales, following upon an outbreak of typhoid fever. In 1882 he decided to commence general practice at Weymouth, and for some 12 years he conducted a large practice in that town and neighbourhood, but again he felt that he had not found the career that most appealed to him. At this time the problems of public health and sanitation became more obviously attractive to the medical man with special scientific equipment. In 1895 Childs acquired the diploma of D.P.H. at Cambridge, and left Weymouth for Manchester-square to practise as a sanitary expert. He was accepted quickly as an authority, wrote ably upon epidemiological subjects, and in particular made some comparative studies of typhoid fever epidemics which well represented the knowledge of the time. He lectured on bacteriology and hygiene at University College, London, and examined in those subjects for the English Conjoint Board.

He retired, however, while still in middle age, and removed to Looe, where he passed the last twenty-four years of his life devoting himself to the public welfare of the town, and, indeed, of his native county, being particularly interested in the fortunes of the Cornish fishing industry and the promotion of ambulance work. He was a Knight of Grace of the Order of St. John of Jerusalem.

One who had been his pupil at Uppingham writes: "Childs was a man whom those of his juniors who came into contact with him will always remember as an old friend. Uppingham, during his brief term of office as a science master, was mainly a classical school, and it is doubtful if Childs would have occupied a position of real authority among us had it not been for his personal kindliness and his record on the playing field as athletic champion and captain of football. But the few of us who worked under him in his simply equipped laboratory gained an insight into the beginnings of scientific work which made the later approach to serious study far easier for us."

Dr. Childs married Miss Anne MacRea, of Weymouth, who predeceased him, and by whom he had one son.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt. S. G. Rainsford to be Surg. Lt.-Comdr.

The following appts. are notified: Surg. Rear-Admiral H. C. Whiteside is placed on books of *President* while attending conference of Association of Military Surgeons of the United States. Surg. Comdrs: F. C. Wright to *Vindictive*; A. C. Anderson to *Argus*; J. Bourdas to *Victory* for R.N. Barracks, Portsmouth; and H. M. Langdale to *Vernon*. Surg. Lts. E. T. S. Rudd to *Pembroke* for R.M. Infirmary, Chatham; T. Rees to *Hood*; A. S. Nicol to *Impregnable*; D. R. Campbell, L. J. Corbett, and S. J. Savage to *Broke* (on recommg.). Surg. Lt.-Comdr. (D.) B. J. Geekie to *Malabar* for R.N. Hospl., Bermuda.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. W. C. Croly retires on retd. pay.

Maj. C. Clarke, Reg. Army Res. of Off., relinquishes his appt. and resumes the rank of Lt.-Col.

The undermentioned Lts. (on prob.) are confirmed in their rank: F. McL. Richardson, J. W. Eames, and S. R. M. Mackay.

TERRITORIAL ARMY.

Capt. E. White (late R.A.M.C.) to be Lt. and relinquishes the rank of Capt.

W. F. Mulvey to be Lt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Lt.-Col. A. Greenwood, having attained the age limit, relinquishes his commn. and retains his rank.

ROYAL AIR FORCE.

Flight Lt. H. W. Corner is granted a permanent commission in this rank.

Capt. W. R. Wotton (Army Dental Corps) is granted a temporary commission as a Flight Lt. (Dental) on attachment to the R.A.F.

Flight Lt. (Hon. Sqdn. Ldr.) J. W. H. Steil relinquishes his temporary commission on completion of service and is permitted to retain his rank.

INDIAN MEDICAL SERVICE.

C. L. Noble to be Lt.

Sunderdas Tulsidas Sodah to be Temp. Lt.

ROYAL ARMY MEDICAL COLLEGE.

The following prizes were awarded at the conclusion of the summer course for Lieutenants on probation, R.A.M.C., and I.M.S., at the Royal Army Medical College, Grosvenor-road, London, S.W.: Herbert prize (about £20): Highest aggregate marks, Lt. F. McL. Richardson, R.A.M.C. First Montefiore prize (£20 and bronze medal): Highest marks in military surgery, Lt. A. McMillan, R.A.M.C. Second Montefiore prize (£7): Second highest marks in military surgery, Lt. S. S. Bhatnagar, I.M.S. Parkes Memorial (medal and £5): Highest marks in hygiene, Lt. F. McL. Richardson, R.A.M.C. Ranald Martin (medal and £5): Highest marks in tropical medicine, Lt. F. McL. Richardson, R.A.M.C. Tulloch Memorial (silver medal): Highest marks in pathology by an R.A.M.C. officer, Lt. G. T. L. Archer. Fayrer Memorial (bronze medal): Highest marks in pathology by an I.M.S. officer, Lt. C. J. F. Cropper. De Chaumont prize: Second highest marks in hygiene, Lt. S. R. M. Mackay, R.A.M.C.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

CHANGES IN PENSIONS ADMINISTRATION.

BEFORE the prorogation of Parliament, on Friday, August 3rd, some important questions of policy in the assessment of post-war disability pensions and the medical treatment of pensioners came up.

On the motion for the third reading of the Consolidated Fund (Appropriation) Bill,

Sir ROBERT HUTCHISON said, in view of the important statement made by the Minister of Pensions recently, he took that opportunity of raising some important points. There was one point in the statement on which he would like some elucidation—namely, the question of allowances for treatment. They had now got so far away from the war that many of those who were still suffering from wounds, from the affects of gas, and from nervous disability could be considered chronic, and their condition was on quite a different plane from what it was ten years ago. He suggested that there were a great many cases which would be much better cared for in regular institutions where their condition might be ameliorated. They knew of cases where people had been sent for treatment again and again by medical boards, and the nervous exhaustion of the individuals who had to undergo that treatment, and in some cases operations, was pitiful. Some attention ought to be given to this very serious matter. His next point was as to the continuance of re-examination before medical boards for re-assessment of pensions in quite a small number of cases. The argument was used that after a final assessment and the giving of a final pension there were cases that got worse; but statistics would prove that almost 95 per cent. of the cases that had been given final awards did not come up for re-assessment. It seemed to him that the time had arrived when the Ministry should deal generously with the remaining cases, and give them a final pension, even though it might be to the detriment of the State. The amount of money involved must be small compared with the total expenditure. The Government might also consider a definite proposal for closing down the Ministry of Pensions step by step over a period of a few years. Large blocks of people could be given a statutory right to their pensions which would be paid through the Post Office, and the cases which fell for continual attention might be handed over to institutions, or to the care of the medical authorities through the Ministry of Health. In that way money could be saved in a direction in which, at present, there was extravagance considering the work which had to be done. The statement made by the Minister as to the stabilisation of pensions had gladdened the hearts of many, but the more they could close down the Ministry the better it would be for all concerned.

Mr. F. ROBERTS said that the House agreed that the Government had taken the right and proper course in the stabilisation of war pensions. He would offer resistance to Sir R. Hutchison's proposal with regard to the closing down of the Ministry of Pensions. They recognised that there must be some contraction of the work, but the more they looked around the more they understood how big the question was that confronted them, and how important it was to have a Minister in the House of Commons who could be questioned in regard to the problems affecting ex-Service men. It was essential to maintain this Department, with its voluntary workers and officers throughout the country, in order to keep in operation that human touch which was more necessary in connexion with pensioners than perhaps any other department of our social life. If the Minister of Pensions and the Government were not prepared to accept the view that there should be no time limit, and that if a man was suffering from a war disability, he should thereby be entitled to pension, then he (Mr. Roberts) would ask the right hon. gentleman to what extent he was prepared to go in meeting the needs of those neurasthenic and tuberculous cases which from time to time were such a source of great anxiety. He would also like to ask the Minister whether it was his intention to provide special treatment for border-line cases, in regard to which it was doubtful whether the policy applied was that which Parliament and the country desired.

The Future of the Ministry of Pensions.

Lieut.-Colonel FREMANTLE said he would like to speak from the point of view of the medical service and medical administration in the Ministry of Pensions. It was sometimes forgotten that the Ministry of Pensions was a most influential part of the health services of the nation, although it was divorced from the general health services. They were all immense admirers of the Minister of Pensions and the work of his staff, but the stoutest defender of the Ministry as a separate entity must admit that it would come to an end one of these days, and it was right that they should envisage the future and try and consider to what extent it was likely to be changed. After they had stabilised the greatest number of pensions this largely became a medical question. From the medical point of view one obviously supposed that before the general body of pensioners had passed into another world rather than have the whole system of treatment of the few that remained die of inanition, the duties of the Department would have to be passed over to some other Department, and the question was how soon that should take place. It was quite true that that was not a question of immediate politics; but it was obvious that sooner or later the responsibility for the institutions and the personnel would have to be transferred. The natural body to complete and wind up the service would seem to be the Ministry of Health, but that would associate itself in their minds with the poor-law guardians, and there had always been a great and natural reluctance to imagine the possibility of in any way fusing this service with the service of the poor-law guardians. The proposal of the Government in the big Bill foreshadowed for next session was, however, to transfer the whole system of the poor-law into the hands of larger authorities—the county councils and the county borough councils—and he thought they would there have a new envisagement of institutional treatment and public health. They would have larger authorities possessing an enlarged service of institutions with a very large field of employment; because, if the new Bill passed substantially in the form in which it was proposed, they would be taking over the whole of the services of that kind, whether they were in the hands of the guardians or those of the district sanitary authorities. He was not going to say straight away that that in itself would qualify them to take over, or operate, the services of the Ministry of Pensions, but it was obvious that it gave them a prima facie reason for believing that they would be the body for that purpose. All that, however, was in the future, and they would, first of all, have to see how this reform worked out. When the counties had produced their schemes and got to work for a year or two, it would be possible to judge whether they would be able to relieve and help the Ministry of Pensions in this work. The Minister would have to consider what was to be the future of his institution and his personnel. The personnel must be a gradually diminishing one, but it would be a very difficult thing to know how to deal with it. There was a whole series of eminent medical men who had given themselves up to the Pensions service, who were chosen for work at the end of the war as the result, perhaps, of their war service, and it would be a difficult thing to turn those men out of the service and give them no future at all. In the same way with institutions; it would be a bad thing to see institutions contracting and becoming less efficient while they had to undertake big schemes for their fusion with all the geographical difficulties that would entail on pensioners and in other directions. Therefore, it was right that the Ministry should envisage the possibility of bit by bit gradually working in and coöporating with the Ministry of Health, and eventually the county and county borough councils, for the gradual fusion of the two services for which, in so far as pensions were concerned, the Ministry of Pensions would naturally retain its responsibility. Only at a later stage would the Minister transfer the institutions to the Ministry of Health.

They had to consider yet another side, and that was the future of the whole of these institutions with their personnel, and this service which had been built up by the present Minister of Pensions and his predecessors. They had developed a new medical science. This subject of the assessment of liability and the attributability of disease to war, with all its difficulties, had been developed by this service, and had become a fine art akin only to the medical service in connexion with insurance. It would be invaluable to the nation as a whole. The institutions with their specialist forms of treatment, as well as their general forms of treatment, had attained a very high professional position, and a high degree of skill and equipment. The great pity was that that should not be made available to the civil population in the future. If the personnel and the institutions were left gradually to slide down and down, though living an independent life, they would lose their standing and value in a large degree before they were transferred to the civil side. The Minister of Pensions should be considering in what way he could coöperate with the Ministry of Health and the other civil authorities in catering for some of the civil needs of the population, and in that way help to keep alive his institutions and maintain them at their highest possible pitch of fitness.

Dr. DRUMMOND SHIELS said he was unable to join in th mild congratulations which had been generally given to th

Minister, because he was thoroughly dissatisfied both with the policy and the spirit of the Ministry of Pensions. He agreed that it was very desirable that they should have had an intimation that week on the stabilisation of pensions, although *in effect* it only meant that after 1931 the present position of pensions was to continue. He did not criticise the present Minister specially, except that he thought he had been more accommodating to pressure from the Treasury than any other Pensions Minister. The Pensions Ministry had been under the domination of the Treasury ever since January, 1920. He could bring forward any number of cases which had gone through his hands where men had undoubtedly suffered in health very seriously because of the war but were receiving no pension, or only a miserable pension. Lieut.-Colonel Fremantle had spoken about the medical point of view. He (Dr. Shiels) was not particularly concerned at present about the future organisation of the Ministry. The medical point of view in which he was interested in connexion with the Ministry of Pensions was the way in which the Ministry turned down the opinions of medical men, not only panel doctors, many of whom were extremely and naturally indignant, but also well-known specialists, whose opinion was flouted by the Ministry of Pensions. He was not sure that it was by the medical men in the Ministry of Pensions. The medical men in the Ministry were not supreme. But they all knew of cases where a man was told that his case was one which made home treatment suitable; he did not require any hospital treatment, but his case could be dealt with by his panel doctor. He went to the panel doctor, and the panel doctor examined him and said that in his opinion the man required either hospital treatment or specialist treatment, and sent him back to the Ministry. Then the man was pushed backwards and forwards and was refused the treatment which the panel doctor thought was desirable. Even the opinions of medical specialists were set aside. He (Dr. Shiels) thought the Ministry of Pensions should give more heed to the opinions of conscientious medical men who knew the patients, and in many cases knew them before the war, and who understood the change that had taken place.

Mr. MONTAGUE said he did not altogether agree with Dr. Shiels in reference to the point raised by Lieut.-Colonel Fremantle, because he thought that Colonel Fremantle's reference to the use of an efficient State medical service for the civil population was a very big advance towards the point of view that the Labour Party held in regard to medicine and the nation as a whole.

The Minister's Reply.

After further debate,

Major TRYON, Minister of Pensions, said that as a result of the work of a committee presided over by Sir Godfrey Collins, the problem of artificial limbs for ex-Service men had been most satisfactorily settled. He believed that the limbs now supplied were probably the best supplied by any country which took part in the war. He had seen a suggestion that the 6000 men who had lost their reason would get nothing if it was not for the ex-Service Men's Welfare Society. That was a statement which no doubt enabled the Society to obtain funds from the charitable public, but it was absolutely untrue, because that Society under the law was not able to deal with a single one of the 6000 mentally afflicted men in the asylums; and so far from it being the case that the State had done nothing for them, the State had for many years past been spending about £3,000,000 a year on mental cases alone. The doctors of the Ministry were doing a wonderful work for these cases. He did not think the country generally realised how much the ex-Service men owed to the wonderful work which had been done for the sick and disabled by the medical staff of the Ministry. It was true, as Colonel Fremantle had said, that medical science had advanced, and he was glad to see that in a hospital which had hitherto been doing much work for the ex-Service men the great experience gained in connexion with the loss of limbs had been used to help railway men who had lost their limbs in civil employment. In that way they hoped to carry on the medical experience gained through these terrible sufferings, in order that the knowledge so obtained might be of assistance in civil life to other sufferers.

The Bill was read the third time.

SHEFFIELD PENNY-IN-THE-POUND SCHEME.—It is officially stated that this fund will this year be able to distribute £100,000 among the four Sheffield hospitals. Last year the amount so distributed was £88,809, out of a total of £116,816. The balance was expended upon the ambulance, convalescent, and other services. At the end of 1927 the joint debt of the Sheffield hospitals was £59,000 as against £111,000 twelve months earlier.

THE HEART AND CIRCULATION IN BERI-BERI.

To the Editor of THE LANCET.

SIR,—In the St. Cyres lecture, published in your last issue, Prof. Wenckebach has dealt with the problems of the beri-beri heart, and has supplied a most interesting and suggestive explanation of the difficulties met with. At the same time he has introduced a new view of the mechanics of the heart and circulation in connexion with the action of the right and left ventricles. This new view may be correct, but as its acceptance entails the dropping of well-established beliefs some caution is required.

The leading features of the beri-beri heart would appear to be dilatation and weakening of the right ventricle, weakening of the left ventricle, increasing stasis in the liver and venæ cavæ, and a pulmonary *circulation completely free from any sign of stasis.* These phenomena taken by themselves would suggest a condition of congestive heart failure, but Prof. Wenckebach has accepted the statements of the authorities on this disease that the chief lesion is in the right ventricle, and that the circulatory disturbances are due to its failure. He says that clinical experience has taught him "that in cases of increasing insufficiency of the whole heart the right heart is doomed beforehand to suffer much more than the left, and even to suffer to the profit of the latter." This can only be tested by the effect on the circulation. In cases of the beri-beri heart the pulmonary circulation goes on unimpaired, so that one *may* assume an efficiency of action and an absence of suffering as regards the right ventricle. On the other hand, congestion of the liver and large veins, with a feeble apex beat and a weak, rapid pulse, suggests that it is the left ventricle which is in difficulty. The teachings of clinical experience as given above may be right or may be wrong, but they do not seem to find much support in the clinical features of the beri-beri heart.

The great function of the right ventricle is to carry on the pulmonary circulation. In the beri-beri heart the weakened and dilated right heart develops incompetence of the tricuspid valve; Prof. Wenckebach says that "blood passes from the right heart backwards into the veins and liver, and the arterial output of the right ventricle is greatly reduced." Here we have the back-pressure theory in all its nakedness, but in spite of this failure of the right heart, "there is no lung stasis, no râles, and no pulmonary œdema." In short, this disabled and dilated right ventricle is carrying on its normal function most efficiently, and at the same time is doing extra work in pumping the blood back into the venæ cavæ and liver until they are gorged with blood. But this is not all the trouble of the right ventricle. "The right heart has to deal with the whole volume of blood returning from the periphery to the heart, *the left heart not receiving more blood than the right heart is able to transmit.* Consequently the right heart is all the time struggling for life against an ever-increasing overfilling and widening, but the left heart is spared a similar burden." But why this life and death struggle of the right heart? Is it so clear that it is the action of the right heart which has over-distended the venæ cavæ and liver? No action or inaction of the right ventricle can produce such stasis of the venæ cavæ and liver when at the same time an efficient pulmonary circulation is being carried on. One can conceive that the right heart may fail to carry on an efficient pulmonary circulation, with some reflux through the tricuspid valve, or that the right heart may carry on the pulmonary circulation efficiently without such reflux, but one cannot conceive that the right heart should be carrying on the pulmonary circulation successfully and at the same time be pumping the liver full of blood. The closing stages of the beri-beri heart are no less puzzling, for now, at long last, the left ventricle comes into the picture. "At the last moment before death the latter loses its systolic power, succumbs, and leaves the lungs with stagnating blood and signs of ante-mortem œdema." Surely these pulmonary signs are to be traced to a failure in action of the right and not of the left ventricle, and they happen to be the first unequivocal signs of right-sided failure which the lecturer has described in connexion with the beri-beri heart.

Prof. Wenckebach seems to have accepted the statements of the authorities on beri-beri as to the special cardiac changes present, and on this basis he has built a new theory of cardiac physics. He promulgates a new law of the heart as follows: "In equal and increasing feebleness of the whole heart muscle the patient suffers most and dies from the failure of the right side of the heart only." The beri-beri heart may require new views of the circulation and new laws of the action of the two sides of the heart, but there is still something to be said for the old ones. In the beri-beri heart the left ventricle is weakened and the rate is increased. The signs of right-sided failure on which so much stress has been laid might more convincingly be explained by failure of the left ventricle. The engorgement of the liver and large veins, ascribed to the back pressure from the right heart, is now usually ascribed to the diminished forward pressure of the left ventricle. It is the characteristic sign of a failing left ventricle. The total absence in beri-beri of signs of disturbance in the pulmonary circulation—no stasis, no œdema, no dyspnœa—would indicate a right ventricle working at its ease and well within its powers. The arterial output of the ventricle must be quite up to normal, and if at the same time it is pumping blood into the liver, while its muscle is seriously weakened by disease, we have indeed a phenomenon which requires some new law.

Prof. Wenckebach was an honoured guest of the Royal College of Physicians at the recent Harveian celebrations, and saw the demonstration by Sir Thomas Lewis of Harvey's original experiments. Might I suggest that he test the truth of his new views, in the manner of Harvey, by some physiological experiments to show the circulatory correlation between the two sides of the heart? It was not Harvey's theories, but his experiments which carried conviction to the sceptics of his time, and no doubt the same would apply to-day.

I am, Sir, yours faithfully,

London, August 12th, 1928. G. A. SUTHERLAND.

HERPES ZOSTER AND VARICELLA.

To the Editor of THE LANCET.

SIR,—I read with interest the note on p. 264 of THE LANCET, August 4th, and while reports of the development of the two maladies side by side are now too frequent to be of much interest, yet I cannot refrain from mentioning a small epidemic of chicken-pox I saw recently. Occurring as it did in an isolated island district where there was little possibility of outside infection the relationship between the illnesses was very definite.

On Jan. 6th last I was called to see a case of herpes zoster in a woman who had a definite history of previous debility and gastric disturbance. The rash had developed two days before and was unilateral along the course of the right seventh intercostal nerve. On Jan. 12th I was called to see her son aged 25 who had a most profuse and typical varicella with considerable constitutional disturbance, including a sore throat and total suppression of urine for 24 hours. On Jan. 13th a nephew aged 8 years, who had slept with his aunt for several nights and had then returned to his own home about a quarter of a mile away during the week prior to the development of her herpes, developed varicella. He had not been near the house after my visit on Jan. 6th. On Jan. 22nd the child's small brother and sister and a playmate simultaneously developed varicella but showed much less constitutional disturbance.

The cases caused considerable interest and alarm amongst the cottars, who could hardly believe in the origin of chicken-pox. A few years ago my principal had a case of an elderly lady visiting a sick child on her estate. The illness was found to be chicken-pox, and about a fortnight later the lady developed a very severe attack of herpes zoster.

I am, Sir, yours faithfully,

FLORA L. MACDONALD, M.B., Ch.B.,
Assistant General Practitioner.

Isle of Mull, August 11th, 1928.

POST-OPERATIVE MASSIVE COLLAPSE OF THE LUNGS.

To the Editor of THE LANCET.

SIR,—We read with great interest Dr. K. D. Wilkinson's letter in your issue of August 4th (p. 257). In our communication the term collapse is used exclusively in the sense that Pasteur originally intended it—namely, to indicate a complete apneumatosis of the affected lung, deflation being applied to the varying degrees of shrinkage that can occur without complete airlessness. We suspect that Dr. Wilkinson does not intend a similar distinction and this may account, in part, for his attitude towards our theories.

It is recognised that the assumption of the supine position in any circumstances is accompanied by a definite decrease in the vital capacity, or deflation of the lungs. It is our contention that following abdominal operations this is increased by a limitation of the respiratory movements which is partly reflex and partly voluntary in origin. This additional influence is most marked following upper abdominal operations, and for purely mechanical reasons it affects the lower more than the upper lobes, and these in males more than females, but the resulting deflation can never be more extreme than that of forced expiration, and apart from active compression there is only one method by which the lung can become completely airless, that is absorption of the alveolar air following obstruction of the bronchial tree.

The onset of post-operative massive collapse following the obstruction of a bronchus may be insidious, the physical signs when the block is complete being those which have been described as "dead lung." The sign of consolidation appearing only when the obstruction is removed without aeration of the alveolar tissue, but when a lobe which is already deflated becomes collapsed because of the diffuse obstruction of the bronchioles, the initial signs may suggest consolidation, followed later by those of "dead lung," because of the accumulation of secretions, and later still by those of consolidation when these secretions are removed. We think that examination of this hypothesis will explain many of the difficulties which Dr. Wilkinson raises. It is not at variance with a known physiological fact and it does not necessitate the assumption of anything which cannot be confirmed experimentally. We submit, however, that although Dr. Wilkinson's very ingenious theory might account for extreme deflation of the lung it could not account for the absolute airlessness which we regard as an essential of massive collapse.

We have had no personal experience of massive collapse occurring after gun-shot wounds of the chest and elsewhere, but feel that they can be explained by bronchial obstruction, and in this connexion we think that insufficient attention has been given to Curl's observation, that even non-pentrating wounds of the thorax are followed by bronchial hypersecretion which is often almost confined to the opposite lung, due in his opinion to a contrecoup mechanism such as occurs in cranial injuries. Given this hypersecretion and voluntary suppression of the expulsive efforts it is easy to see how bronchial obstruction may arise.

We agree as to the necessity of administering an efficient pre-operative and in some cases a post-operative dose of atropine, and suggest that the favourable reports which Mr. Hamilton Whiteford

Minister, because he was thoroughly dissatisfied both with the policy and the spirit of the Ministry of Pensions. He agreed that it was very desirable that they should have had an intimation that week on the stabilisation of pensions, although in effect it only meant that after 1931 the present position of pensions was to continue. He did not criticise the present Minister specially, except that he thought he had been more accommodating to pressure from the Treasury than any other Pensions Minister. The Pensions Ministry had been under the domination of the Treasury ever since January, 1920. He could bring forward any number of cases which had gone through his hands where men had undoubtedly suffered in health very seriously because of the war but were receiving no pension, or only a miserable pension. Lieut.-Colonel Fremantle had spoken about the medical point of view. He (Dr. Shiels) was not particularly concerned at present about the future organisation of the Ministry. The medical point of view in which he was interested in connexion with the Ministry of Pensions was the way in which the Ministry turned down the opinions of medical men, not only panel doctors, many of whom were extremely and naturally indignant, but also well-known specialists, whose opinion was flouted by the Ministry of Pensions. He was not sure that it was by the medical men in the Ministry of Pensions. The medical men in the Ministry were not supreme. But they all knew of cases where a man was told that his case was one which made home treatment suitable; he did not require any hospital treatment, but his case could be dealt with by his panel doctor. He went to the panel doctor, and the panel doctor examined him and said that in his opinion the man required either hospital treatment or specialist treatment, and sent him back to the Ministry. Then the man was pushed backwards and forwards and was refused the treatment which the panel doctor thought was desirable. Even the opinions of medical specialists were set aside. He (Dr. Shiels) thought the Ministry of Pensions should give more heed to the opinions of conscientious medical men who knew the patients, and in many cases knew them before the war, and who understood the change that had taken place.

Mr. MONTAGUE said he did not altogether agree with Dr. Shiels in reference to the point raised by Lieut.-Colonel Fremantle, because he thought that Colonel Fremantle's reference to the use of an efficient State medical service for the civil population was a very big advance towards the point of view that the Labour Party held in regard to medicine and the nation as a whole.

The Minister's Reply.

After further debate,

Major TRYON, Minister of Pensions, said that as a result of the work of a committee presided over by Sir Godfrey Collins, the problem of artificial limbs for ex-Service men had been most satisfactorily settled. He believed that the limbs now supplied were probably the best supplied by any country which took part in the war. He had seen a suggestion that the 6000 men who had lost their reason would get nothing if it was not for the ex-Service Men's Welfare Society. That was a statement which no doubt enabled the Society to obtain funds from the charitable public, but it was absolutely untrue, because that Society under the law was not able to deal with a single one of the 6000 mentally afflicted men in the asylums; and so far from it being the case that the State had done nothing for them, the State had for many years past been spending about £3,000,000 a year on mental cases alone. The doctors of the Ministry were doing a wonderful work for these cases. He did not think the country generally realised how much the ex-Service men owed to the wonderful work which had been done for the sick and disabled by the medical staff of the Ministry. It was true, as Colonel Fremantle had said, that medical science had advanced, and he was glad to see that in a hospital which had hitherto been doing much work for the ex-Service men the great experience gained in connexion with the loss of limbs had been used to help railway men who had lost their limbs in civil employment. In that way they hoped to carry on the medical experience gained through these terrible sufferings, in order that the knowledge so obtained might be of assistance in civil life to other sufferers.

The Bill was read the third time.

SHEFFIELD PENNY-IN-THE-POUND SCHEME.—It is officially stated that this fund will this year be able to distribute £100,000 among the four Sheffield hospitals. Last year the amount so distributed was £88,809, out of a total of £116,816. The balance was expended upon the ambulance, convalescent, and other services. At the end of 1927 the joint debt of the Sheffield hospitals was £59,000 as against £111,000 twelve months earlier.

"Audi alteram partem."

THE HEART AND CIRCULATION IN BERI-BERI.

To the Editor of THE LANCET.

SIR,—In the St. Cyres lecture, published in your last issue, Prof. Wenckebach has dealt with the problems of the beri-beri heart, and has supplied a most interesting and suggestive explanation of the difficulties met with. At the same time he has introduced a new view of the mechanics of the heart and circulation in connexion with the action of the right and left ventricles. This new view may be correct, but as its acceptance entails the dropping of well-established beliefs some caution is required.

The leading features of the beri-beri heart would appear to be dilatation and weakening of the right ventricle, weakening of the left ventricle, increasing stasis in the liver and venæ cavæ, and a pulmonary circulation completely free from any sign of stasis. These phenomena taken by themselves would suggest a condition of congestive heart failure, but Prof. Wenckebach has accepted the statements of the authorities on this disease that the chief lesion is in the right ventricle, and that the circulatory disturbances are due to its failure. He says that clinical experience has taught him "that in cases of increasing insufficiency of the whole heart the right heart is doomed beforehand to suffer much more than the left, and even to suffer to the profit of the latter." This can only be tested by the effect on the circulation. In cases of the beri-beri heart the pulmonary circulation goes on unimpaired, so that one may assume an efficiency of action and an absence of suffering as regards the right ventricle. On the other hand, congestion of the liver and large veins, with a feeble apex beat and a weak, rapid pulse, suggests that it is the left ventricle which is in difficulty. The teachings of clinical experience as given above may be right or may be wrong, but they do not seem to find much support in the clinical features of the beri-beri heart.

The great function of the right ventricle is to carry on the pulmonary circulation. In the beri-beri heart the weakened and dilated right heart develops incompetence of the tricuspid valve; Prof. Wenckebach says that "blood passes from the right heart backwards into the veins and liver, and the arterial output of the right ventricle is greatly reduced." Here we have the back-pressure theory in all its nakedness, but in spite of this failure of the right heart, "there is no lung stasis, no râles, and no pulmonary œdema." In short, this disabled and dilated right ventricle is carrying on its normal function most efficiently, and at the same time is doing extra work in pumping the blood back into the venæ cavæ and liver until they are gorged with blood. But this is not all the trouble of the right ventricle. "The right heart has to deal with the whole volume of blood returning from the periphery to the heart, *the left heart not receiving more blood than the right heart is able to transmit*. Consequently the right heart is all the time struggling for life against an ever-increasing overfilling and widening, but the left heart is spared a similar burden." But why this life and death struggle of the right heart? Is it so clear that it is the action of the right heart which has over-distended the venæ cavæ and liver? No action or inaction of the right ventricle can produce such stasis of the venæ cavæ and liver when at the same time an efficient pulmonary circulation is being carried on. One can conceive that the right heart may fail to carry on an efficient pulmonary circulation, with some reflux through the tricuspid valve, or that the right heart may carry on the pulmonary circulation efficiently without such reflux, but one cannot conceive that the right heart should be carrying on the pulmonary circulation leaders of the medical profession? In other words, what is there to prevent a highly respected and representative body of experts from issuing to the public carefully prepared information as to the early signs of cancer? One of the objections most commonly raised is that such an educational campaign would degenerate into scaremongering, and the result would be periodic outbreaks of cancerphobia and new crops of neurasthenics. But however carefully we examine the situation which would arise under such conditions, we cannot find more than two classes of persons concerned—those who are, and those who are not, suffering from early cancer. The first would surely benefit from advice which would lead them to an early medical examination. As for the remainder, they would, if alarmed, in most cases consult a doctor, and in due course be reassured. Another obstacle to an educational campaign is a deep-seated distaste on the part of many doctors to popularising medicine. To some it is a sacred cult, not to be prostituted by widespread publicity. The situation in the world of medicine to-day is curiously similar to the world of theology at the time when Wesley drew his followers from the dim religious light of churches to the secular atmosphere of the hillside. In defence of those who shun the popular health article or lecture as they would pornographic literature, we should remind ourselves that in the past a certain amount of popular health teaching has been undertaken by cranks and persons with some axe to grind. But this class has flourished largely because the field was left open to it by the more respectable members of the medical profession. It does not, however, follow that this field ought itself to be neglected. The presence in it of undesirables should rather be a spur to replacing them by something much better. The leaders of the medical profession who adopt a pose of masterly inactivity in this matter may find it interpreted (or misinterpreted) as a glaring example of timid indolence.

Yet another objection to an educational campaign about cancer is the lack of unanimity among the experts as to even the most elementary matters concerning cancer. They cannot tell the public whether it is infectious or not, hereditary or not. To one all-important question after another they are bound to admit ignorance. It is tempting in such circumstances to wait and see; peradventure the cause and uniformly successful treatment of cancer will be discovered shortly, and then it will be time enough to tell the public. To such arguments in favour of silence there is the unanswerable reply that, to repeat the opening words of this letter, practically everyone is agreed that the earlier cancer is detected, the better are the chances of recovery. And if every woman is taught that a swelling in the breast or an irregular hæmorrhage during the puerperium needs investigation at once by a doctor for fear of its being malignant, many who at present come to a doctor for the first time with an inoperable tumour would be saved. There can be no two opinions on this point. Reserve on the part of the medical profession in this matter may seem lofty and dignified to a few. To candid observers it must seem merely genteel.

I am, Sir, yours faithfully,

August 11th, 1928. D.P.H.

Death of Mr. T. B. Lapworth.—The death occurred on Thursday, August 9th, at the age of 59, of Mr. Trever B. Lapworth, who was for 44 years associated with the *British Medical Journal*, and for 17 years the head printer. He had been in failing health for some time, and will be sadly missed by numerous colleagues and friends.

An Improved Syringe for the Treatment of Varicose Veins.—We understand that the improved syringe which we noticed in our issue of May 19th, p. 1022, is now made in capacities of 3, 5, 10, and 20 c.cm., while its total length has been greatly reduced by increasing the diameter of the barrel and by using only one ampulla in the capillary tube instead of two as previously. The syringe can be obtained from Messrs. Adair, Dutt and Co., 47, Victoria-street, London, S.W.

Medical News.

Medical Society of London.—The programme for the first half of the session 1928–29 has now been issued. On Monday, Oct. 8th, Dr. J. W. Carr will give a presidential address on Medical Ambitions and Ideals; on Oct. 22nd Dr. C. E. Lakin and Mr. Tudor Edwards will open a discussion on the Diagnosis and Treatment of Empyema; and on Nov. 12th Prof. Hey Groves and Dr. James Neal will open a discussion on the Medico-Legal Aspects of Fractures. On Nov. 26th there will be a clinical evening, and the last meeting of the year will be on Dec. 10th, when Dr. Wilfred Harris, Mr. P. J. Verrall, and Dr. James Brailsford will introduce the subject of Sacroiliac Pain. The Lettsomian Lectures will be delivered on Feb. 18th and 27th and March 6th by Dr. H. W. Barber, on Dermatology in Relation to other Branches of Medicine, and the Society's annual oration will be given on May 13th by Prof. Grey Turner, whose subject will be Cancer of the Colon.

Marking of Surgical Instruments and Appliances.—The Standing Committee (General Merchandise) appointed by the Board of Trade have reported on their inquiry as to whether imported surgical, medical, dental, and veterinary instruments and appliances, and dental supplies and furniture should be required to bear an indication of origin. The report, which recommends that an order in council be made requiring the marking of many imported articles at the time of sale or exposure for sale, is obtainable from H.M. Stationery Office, or through any bookseller, price *2d.* a copy.

Royal Sussex County Hospital.—Dame Anne Beadsmore Smith, Matron-in-Chief of the Territorial Nursing Service, recently opened the two new wings which have been added to the nurses' home of this hospital. These extensions will bring the accommodation of the home up to 108 beds, and comprises rooms for the sisters and a large lecture room. A brief service of dedication was performed by Bishop Russell Wakefield, and prizes were presented to the nurses by Miss K. Scott, who has for 27 years been matron of the hospital.

Aberdeen Royal Infirmary.—The Prince of Wales will visit Aberdeen on Aug. 28th, to lay the foundation-stone of the new Royal Infirmary. This will form part of a scheme which will coördinate in one area the services of the Royal Infirmary, the Sick Children's Hospital, the Maternity Hospital, and the University Medical School. The building will cost £400,000, of which about £326,000 has been received.

Stirling Royal Infirmary.—The new Royal Infirmary, which was opened by the Duke and Duchess of York on August 10th, has been erected on 15 acres of ground, being part of Wester Livilands estate, which is situated to the south-west of the town. The site is an ideal one from an infirmary point of view. It forms a great, open plateau, beautifully wooded, and commanding magnificent views of the surrounding country on all sides. The building is two storeys high, and contains four surgical wards of 16 beds each, two medical wards of 16 beds each, and one children's ward of 16 beds, with small side wards in addition. The administration department is placed in the centre of the building. There is also a maternity block, which contains two wards of eight beds each, with two single wards and one two-bed ward, accommodating in all 20 patients.

Centenary of Ancoats Hospital. — On August 11th, 1828, a new "public dispensary" was opened for the districts of Ancoats and Ardwick, which were then suburbs of Manchester. At that time and until about 40 years afterwards patients were treated at their own homes, while out-patients went to the dispensary for advice and medicines. There were then no arrangements for in-patients. In 1872 it was determined to add to the dispensary work "hospital practice," and in 1874 a new hospital with six beds was opened. In 1888 a new wing was added, which brought up the number of beds to 100, with developments in all branches of medical and surgical treatment. Situated as the hospital is in one of the most industrial and thickly populated districts of the city, it is now quite inadequate to the calls made on its services. An X ray department was opened in 1907 and a massage and electricity department in 1913. The board of management have determined to make the centenary celebration the occasion for an appeal for a building fund of £100,000. Land adjoining the hospital has been acquired and plans are ready for an extension with 100 additional beds, a new casualty department, extension of some existing departments, two new operating theatres, and the necessary accommodation for nurses and staff.

gives in his letter may be partly explained by the favourable climatic conditions under which he works and the exclusion of morphia from the routine.

We are, Sir, yours faithfully,
CHARLES R. BOLAND.
J. E. SHERET.

Ancoats Hospital, Manchester, August 8th, 1928.

THE VACCINATION COMMITTEE'S REPORT.

To the Editor of THE LANCET.

SIR,—The report, of which you gave the chief features in your issue of August 4th (p. 233), is a curious document in that its inside bears so little relation to the terms of reference on its outside. We seem to learn from it:—

1. That a certain amount of standardisation of vaccine has been done, but that the relation between any particular vaccinal dose and the immunity conferred by it is unknown.

2. It is recommended that a trial be made of vaccination by one insertion as is done in Canada, instead of by four marks as is at present the law here. Three such vaccinations per person are advocated, the first in infancy, then at school-age, and again between 14 and 16 years of age.

3. It is suggested that vaccination might be performed more aseptically in infant welfare centres than in some homes, and that public vaccinators should inspect their patients twice instead of once.

4. It is stated that vaccination may have some causal responsibility for the encephalitis which occurs ten days after vaccination.

5. Vaccination at epidemic and non-epidemic periods are not considered separately, save that it is assumed, no proof being given, that the revaccinated and those vaccinated in infancy do not contract post-vaccinal encephalitis, and that, therefore, all infants should be vaccinated in order that no person above that age should by primary vaccination run the risk of post-vaccinal encephalitis (a new reason for vaccination, to protect against vaccination).

6. It is stated that their recommendations involve no material change in the instructions to vaccinators under contract—that is, they do not desire any material change in the present methods.

7. It is an expensively printed report, singularly devoid of guidance to those responsible for small-pox and vaccination administration, and though it has taken two and a half years to produce, no attempt has been made to consider the problem from a practical standpoint or to envisage the present conditions.

8. From the reply of the Minister of Health to a Parliamentary question published on the recent bank holiday, it appears that post-vaccinal encephalitis is on the increase. It is therefore a mere question of time before the persons responsible for the vaccination of those children who die of post-vaccinal encephalitis will be considered by some as guilty of constructive murder.

9. Obviously the Committee appointed by the Ministry of Health and the Medical Research Council have regarded themselves as scientific tabulators of facts and have not considered it their function to criticise the department which appointed them. What is wanted now is what I suggested in your issue of Jan. 10th, 1925—namely, a real inquiry into small-pox and vaccination administration in all its bearings by a judge of the High Court; the gentlemen of the late committee should make excellent witnesses, for on the face of their documentary evidence, the sub-department of the Ministry of Health which deals with small-pox and vaccination requires a thorough investigation as to its methods. To cite one question, what is their justification for risking children's lives by vaccination as a protection against a disease which does not imperil their lives? They have, of course, a defence; it should be set out at an inquiry, and its value assessed.

10. The report of the Andrewes Committee of 1923, which only saw the light via the League of Nations about a year ago and is now published in full, should have given the authorities furiously to think. It has not done so, and it is time now that some one, trained to weigh evidence and come to conclusions thereon, should envisage the whole position. No one could better decide how this is to be done than the Lord Chancellor, in his present capacity of acting Prime Minister.

11. A year ago at Hastings I stated my views on the subject printed in No. 4 (1927) of the *Journal of the R.S.I.* The present report and recent happenings seem but to confirm them.

12. The root difficulty has always been that the orthodox regard vaccination as a panacea of universal application, whereas it should be regarded as an insurance proposition, vaccination being only the conferment of a temporary immunity from small-pox which may or may not be worth while under varying conditions. And this difficulty is aggravated by the antivaccinationists who claim that vaccination confers no protection—a manifest absurdity. Supporting their views by many easily refutable arguments they lead the orthodox to a reactive blind acceptance of certain very disputable conclusions.

I am, Sir, yours faithfully,
R. W. JAMESON.

West Wickham, Kent, August 14th, 1928.

EPHEDRINE.

To the Editor of THE LANCET.

SIR,—I have recently been treating several patients with low blood pressure by ephedrine hydrochloride (Burroughs Wellcome and Co.) in doses of gr. $\frac{1}{2}$. In the majority of cases the patients have complained of giddiness and feeling ill after this. These symptoms appear half to one hour after taking the ephedrine, and seem to last about two hours. I have found that gr. $\frac{1}{3}$ or $\frac{1}{4}$ seems to produce a very satisfactory rise in pressure and no toxic symptoms.

I am, Sir, yours faithfully,
H. W. HALES.

Sheringham, Norfolk, August 14th, 1928.

"FUSSING OVER CANCER."

To the Editor of THE LANCET.

SIR,—At the last session of the International Conference on Cancer, the president warned enthusiasts to beware of fussing over public health, or so, at least, it seems from your summary of this meeting (THE LANCET, July 28th, p. 182). Point was given to his admonition by a statement made by Dr. Stanley Reimann, of Philadelphia, to the effect that he could find no indication of the educational campaign of the last 15 years having had any effect. And yet, Sir, if there is one point in regard to cancer on which practically everyone is agreed, it is that the earlier cancer is detected, the better are the patient's chances of recovery. It might be inferred from this conclusion, so obviously true as really to be a truism, that cancer campaigns throughout the world would devote much of their energies and resources to shortening the interval between the first signs of the disease and the treatment thereof. Why, it may be asked, is there a certain hesitancy in pursuing this matter to its logical conclusion, and in launching educational campaigns with regard to cancer? There are two phases of the period which ends with the commencement of treatment. The first phase lasts from the appearance of the first signs of cancer to the first medical examination, usually made by a general practitioner. The second phase dates from this examination till expert treatment is instituted. For the sake of brevity, I limit myself to a consideration of the first phase.

What are the objections to a publicity campaign conducted anonymously in the lay press by the leaders of the medical profession? In other words, what is there to prevent a highly respected and representative body of experts from issuing to the public carefully prepared information as to the early signs of cancer? One of the objections most commonly raised is that such an educational campaign would degenerate into scaremongering, and the result would be periodic outbreaks of cancerphobia and new crops of neurasthenics. But however carefully we examine the situation which would arise under such conditions, we cannot find more than two classes of persons concerned—those who are, and those who are not, suffering from early cancer. The first would surely benefit from advice which would lead them to an early medical examination. As for the remainder, they would, if alarmed, in most cases consult a doctor, and in due course be reassured. Another obstacle to an educational campaign is a deep-seated distaste on the part of many doctors to popularising medicine. To some it is a sacred cult, not to be prostituted by widespread publicity. The situation in the world of medicine to-day is curiously similar to the world of theology at the time when Wesley drew his followers from the dim religious light of churches to the secular atmosphere of the hillside. In defence of those who shun the popular health article or lecture as they would pornographic literature, we should remind ourselves that in the past a certain amount of popular health teaching has been undertaken by cranks and persons with some axe to grind. But this class has flourished largely because the field was left open to it by the more respectable members of the medical profession. It does not, however, follow that this field ought itself to be neglected. The presence in it of undesirables should rather be a spur to replacing them by something much better. The leaders of the medical profession who adopt a pose of masterly inactivity in this matter may find it interpreted (or misinterpreted) as a glaring example of timid indolence.

Yet another objection to an educational campaign about cancer is the lack of unanimity among the experts as to even the most elementary matters concerning cancer. They cannot tell the public whether it is infectious or not, hereditary or not. To one all-important question after another they are bound to admit ignorance. It is tempting in such circumstances to wait and see; peradventure the cause and uniformly successful treatment of cancer will be discovered shortly, and then it will be time enough to tell the public. To such arguments in favour of silence there is the unanswerable reply that, to repeat the opening words of this letter, practically everyone is agreed that the earlier cancer is detected, the better are the chances of recovery. And if every woman is taught that a swelling in the breast or an irregular hæmorrhage during the puerperium needs investigation at once by a doctor for fear of its being malignant, many who at present come to a doctor for the first time with an inoperable tumour would be saved. There can be no two opinions on this point. Reserve on the part of the medical profession in this matter may seem lofty and dignified to a few. To candid observers it must seem merely genteel.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.

Special two weeks Course in Infants' Diseases at the Infants Hospital, Vincent-square, Westminster.

SECOND WEEK.

MONDAY, August 20th.—2 to 3 P.M., Dr. W. E. Robinson: Chest Cases. 3 to 3.45 P.M., Miss Hughes (Matron of the Hospital): Lecture-Demonstration, Notes on Nursing Sick Infants. 4 to 5 P.M., Dr. Eric Pritchard: Lecture-Demonstration, Dried Milks and Patent Foods.

TUESDAY.—2 to 3.45 P.M., Dr. Eric Pritchard: Feeding Cases. 4 to 5 P.M., Mr. Philip Franklin: Lecture, Nasal Discharge and Sinusitis.

WEDNESDAY.—2 to 3 P.M., Miss Hughes: The Making-up of Feeds. 3 to 3.45 P.M., Dr. Eric Pritchard: Lecture-Demonstration, Infants' Stools. 4 to 5 P.M., Dr. C. C. Okell (at the Wellcome Physiological Research Laboratory, 25–28, Endsleigh-gardens, Gordon-square, W.C.): Diphtheria Prophylaxis.

THURSDAY.—2 to 3 P.M., Dr. Eric Pritchard: Feeding Cases. 3 to 3.45 P.M., Dr. Eric Pritchard: Lecture-Demonstration, Minor Ailments. 4 to 5 P.M., Mr. B. S. Simmonds: Lecture, Surgical Emergencies.

FRIDAY.—2 to 3.45 P.M., Dr. Eric Pritchard: Feeding Cases. 4 to 5 P.M., Dr. M. Maizels: Pathological Lecture, The Regulation of Hydrogen-ion Concentration.

SATURDAY.—2 P.M., Visit to Model Pasteurising Plant, Willesden, and to the Nursery Training School, Welgarth-road, Hampstead.

Appointments.

CROSSE, H., M.D., C.M. Edin., has been appointed a Medical Referee for the Districts of the Aylsham, Downham Market, East Dereham, Fakenham, Holt, King's Lynn, North Walsham, Norwich, Swaffham, Thetford, and Wymondham County Courts.

FACEY, R. VAUGHAN, M.B., Ch.B. Oxf., Medical Officer in charge V.D. Department, Royal Victoria and West Hants Hospital, Bournemouth.

MUSGRAVE, J. A., L.R.C.P.I., L.R.C.S.I., D.P.H., Medical Officer of Health for the County Louth.

Certifying Surgeons under the Factory and Workshop Acts: CONNOLLY, C. V., M.B., B.Ch. N.U.I. (Rothwell); and WALKER, F., M.B., Ch.B. Edin. (Falkland, Fife).

Vacancies.

For further information refer to the advertisement columns.

Aberystwyth, Aberystwyth Infirmary and Cardiganshire General Hospital.—H.S. £200.

Bath, Royal United Hospital.—H.P., H.S., and Asst. H.S. At rate of £120 and £100 respectively.

Bedford County Hospital.—H.S., also Asst. H.S. At rate of £175 and £130 respectively.

Birmingham, General Hospital.—Med. Reg. and Res. M.O. £155.

Blackburn and East Lancashire Royal Infirmary.—Res. H.P. Also Fourth H.S. £150 and £130 respectively.

Bradford, Municipal General Hospital (St. Luke's).—H.P.'s and H.S.'s. Each at rate of £200.

Bristol General Hospital.—H.P.'s, H.S.'s, &c. All at rate of £100.

Bristol Royal Infirmary.—H.P.'s, H.S.'s. Also Dental H.S. Each at rate of £80.

Cardiff, University College.—Lecturer and Demonstrator in Anatomy. £400.

Carmarthen, Joint Counties Mental Hospital.—Jun. Asst. M.O. £300.

Chiswick General Hospital, The Mall, Chiswick, W.—Hon. Surg. Also Asst. Hon. Anæsthetist.

Colchester, Severalls Mental Hospital.—Jun. Asst. M.O. £510.

Croydon County Borough.—Asst. M.O.H., &c. £600.

Dreadnought Hospital, Greenwich.—Surg. to Out-patients.

General Lying-in Hospital, York-road, Lambeth, S.E.—Res. M.O. At rate of £100.

Grove Park Hospital, Lee, S.E.—Sen. Asst. M.O. £650.

Hastings, Royal East Sussex Hospital.—Hon. Co-opted Dental Surgeon.

Hospital for Tropical Diseases, Endsleigh-gardens, W.C.—H.P. At rate of £110.

[illegible] Borough of—M.O.H. and School M.O. £800.

[illegible] *rrey County Sanatorium, Milford, near* [illegible] sst. Res. M.O. £500.

Le[illegible] *Committee.*—Asst. School M.O. £600.

Leicester Royal Infirmary.—Res. M.O.'s. Each at rate of £125.

Lincoln County Hospital.—Jun. H.S. At rate of £150.

Manchester, Hulme Dispensary, Dale-street.—Res. M.O. £

Manchester, Park Hospital, Davyhulme.—Three R.M.O.'s. One at rate of £150 and two at rate of £120.

Market Drayton, Salop, Cheshire Joint Sanatorium.—Asst. M.O. £250.

Newport, Mon., Cefn Mably Hospital, Michaelstone-y-vedw.—Asst. Res. M.O. £200. Also Third Asst. Res. M.O. at South Wales Sanatorium, Talgarth, near Brecon. £2[illegible]

Norwich, Norfolk and Norwich Hospital.—Hon. Asst. Phys.

Nottingham City.—M.O.H. £1440.

Nottingham City Mental Hospital.—Jun. Asst. M.O. £350.

Plymouth, Homœopathic and General Hospital.—H.S. At rate of £100.

Plymouth, South Devon and East Cornwall Hospital.—H.S. At rate of £50.

Rotherham, Rotherham Hospital.—H.P. £180.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—H.S. At rate of £100.

Southampton Parish Infirmary, Shirley Warren.—Second Asst. Res. M.O. £275.

Swansea General and Eye Hospital.—Sen. Res. O. £250.

Wandsworth Borough Council.—Locum Tenens, Asst. M.O.H., &c. £10 10s. weekly.

West London Hospital, Hammersmith-road, W.—Non-Res. Cas. O. £5 5s. per week. Also H.P. and two H.S.'s. Each at rate of £100.

Western Australia Lunacy Dept.—Jun. Asst. Res. M.O. £456.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Eastbourne, Sussex; and at Wendron, Cornwall.

Births, Marriages, and Deaths.

BIRTHS.

CARSON.—On August 2nd, the wife of Dr. Hugh Carson, the Hospital, Selly Oak, Birmingham, of a daughter.

GILES.—On August 9th, at York House, Stourport, Worcs., the wife of Dr. O. Pemberton Giles, of a son.

MATHEWSON.—On July 31st, the wife of Dr. W. R. Mathewson, Netherhill, Aberdour, of a daughter.

ROBB.—On August 12th, at Lodge Farm, Melton, Suffolk, the wife of Captain Campbell Robb, R.A.M.C. (retd.), of a son.

RUSSELL.—On August 4th, at Tooting Bec-gardens, Streatham, S.W., the wife of Dr. C. M. Russell, of a son.

TIVY.—On August 7th, the wife of Dr. Eric Tivy, of North Woolwich-road, Silvertown, of a daughter.

TODD.—On August 10th, at Cuckfield, Sussex, the wife of H. C. Todd, F.R.C.S., of a daughter.

WHITEHEAD.—On August 4th, at York Mansions, S.W., the wife of Major N. T. Whitehead, R.A.M.C., of a daughter (stillborn).

MARRIAGES.

ARNOTT—HOWDEN.—At St. Columba's Church, Crieff, Perthshire, *on August 8th, by the Rev. N. J. N. Gourlie,* M.A., Maurice James, only son of Dr. and Mrs. James Arnott, of Brampton, Cumberland, to Jean Skeffington, elder daughter of Emeritus Professor and Mrs. Robert Howden, of Broomfield, Crieff (formerly of Newcastle-upon-Tyne).

CAPELL—DREW.—On August 11th, at St. Mary Abbots, Kensington, Dr. L. F. Capell, of Cricklewood-lane, N.W., to Dorothy Edith, only daughter of the late William Godson Drew, of Hove, Sussex.

LORRAINE—WILSON.—On August 9th, at St. Mary's Parish Church, Knebworth, J. C. Lorraine, M.D., F.R.C.S. Edin., of Montpelier-square, S.W., to Alicia Hill, daughter of Mr. and Mrs. Wm. Wilson, of Knebworth.

SELLORS—LYELL.—On August 8th, at St. Jude's Church, Kensington, Thomas Holmes Sellors, B.M., B.Ch., M.A., to Brenda Murray, daughter of Mrs. W. D. Lyell, Courtfield-gardens, S.W.

THOMAS—NEWCOME.—On July 31st, at St. Gabriel's Church, Warwick-square, London, Ellis Rae Thomas, M.D., M.R.C.S., L.R.C.P., to Lilian Gladys, fourth daughter of the late Chester Pern Newcome, of Long Clawson, Leicestershire.

DEATHS.

CAMBRIDGE.—On August 12th, at Crouch Hill, Thomas Arthur Cambridge, M.R.C.S., L.S.A., aged 82.

CHILDS.—On August 6th, at Rock House, West Looe, Cornwall, Christopher Childs, M.D., aged 81.

DAVIDSON.—On August 11th, at Over Frays, Uxbridge, John Davidson, M.B., aged 70.

EASTES.—On August 8th, at Manor-road, Folkestone, Thomas Eastes, M.D., aged 78.

GREY.—On August 10th, at Harrold, Bedfordshire, suddenly, from pneumonia, Egerton Charles Grey, M.A. Camb., D.Sc. Lond., M.R.C.S., L.R.C.P., F.I.C., late of Cairo.

KERSWILL.—On August 10th, at Sackville House, Sandwich, Harry Kerswill, M.R.C.S., L.R.C.P., aged 60.

OAKDEN.—On August 12th, William Marshall Oakden, B.A., M.B., B.Chir. Camb., F.R.C.S. Eng., Medical Superintendent of St. Luke's Hospital, Lowestoft, aged 41.

TUXFORD.—On August 8th, at Wide Bargate, Boston, Arthur Tuxford, J.P., M.D., aged 87.

WHERRY.—On August 12th, at Cambridge, George Edward Wherry, F.R.C.S., aged 76.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

NOTES ON THE SLACK ABDOMINAL WALL.

BY LIEUT.-COLONEL J. K. MCCONNEL, D.S.O., M.C.,

MEMBER OF THE CHARTERED SOCIETY OF MASSAGE AND MEDICAL GYMNASTICS.

THE following aims at placing the treatment of this condition on to a scientific basis; it is hoped thus to avoid the criticism in Allbutt and Rolleston's "A System of Medicine": "The treatment ceases and, when a sufficient time has elapsed to undo the good which has been done, the patient becomes as bad as ever." The writer asks forgiveness for the extensive quotations in the following lines, but he feels it important to base his arguments on sound authority.

When one investigates this subject, one is in danger of becoming bogged in the voluminous literature that discusses ptosis of the abdominal contents—either severally or collectively. A direct attack on the viscera themselves has not led to very gratifying results and, as is stated in "Modern Medicine" (Osler and McCrae): "The treatment is in the main rather unsatisfactory. . . ."

In order to concentrate our attention on the musculature of the weak abdominal wall, let us take as a simile a motor tyre in which a bulge has appeared. Supposing one finds no replacement at the nearest garage, one may instruct the mechanic to insert a sleeve between the two tubes. In these circumstances no one would blame the air inside for having caused the distressing symptoms, but one would do one's best to overcome the defect in the outer cover and render it an adequate support for its contents.

In the same way several authorities have noted the disappearance of symptoms of visceroptosis, when a suitable support has been applied. Prof. Starling stated: "These viscera in the normal condition are pressed against the under surface of the diaphragm by the elasticity of the abdominal wall." Sir Arthur Keith[1] states: "Now, as is well known, when a living subject raises his body to the sitting or standing posture, the upper viscera do not drop more than ½ or ¾ in.; the ligaments and mesenteries can therefore take no part in sustaining the viscera. The supporting structures are the muscles of the belly wall; particularly is the transversalis muscle important in this respect; it is a living belt which girds the loins."

Let us now leave the viscera and turn our attention to the abdominal wall.

Muscle Action.

Before pursuing the argument it seems advantageous to summarise certain characteristics of muscles. Prof. Starling, in his "*Principles of Human Physiology*," wrote as regards muscular tone: "Every muscle in the body is in a condition of slightly continued contraction which keeps it tense, so that when it contracts in response to a stimulus, there is, so to speak, no "slack" to be taken up before the muscle begins to pull on its attachments. . . . The tone of the muscles is a reflex phenomenon and is dependent on the integrity of the reflex arc governing the muscles in question. It has been shown by Sherrington that the afferent part of the arc is represented by the afferent nerves from the muscle itself. . . . To this system of afferent nerves Sherrington has given the name of the proprioceptive system, since it is excited, not directly by changes in the environment, but by alteration in the animal itself."

A muscle may act in four ways. It may remain at rest, may contract, may "hold," or may relax. Patients sometimes think that muscles can push; at least, they explain movements in terms that would necessitate this. Contraction may take place actively, as when causing a movement, or as a passive shortening, when the energy required for a movement is supplied by some outside force—e.g., gravity—another person, a spring, &c. During an active contraction energy produced by a muscle is impressed on the system to which it belongs through the medium of its attachments or else hydrostatically. As an example of the latter we may take: "The contractions of the skeletal muscles squeeze the veins contained within them, and drive the blood on towards the heart."[2]

Following the classification of muscles in a normal act[3] as given by Dr. Kinnier Wilson, we find:—

1. *Prime movers, or agonists*, which initiate the act.
2. *The antagonists*, which would tend to interfere with the above movement, if they were not reciprocally inhibited.
3. *Synergic muscles* (synergists), which neutralise undesired actions, as when a prime mover, by passing over two or more joints, might give two or more actions, one being desired.
4. *Fixation muscles* (fixers), which provide firm origins from which the others may act.

In a firm closure of the fist the agonists are the flexors of the thumb and fingers, and antagonists are the extensors of the same; as synergists we find the extensors of the wrist, and as fixers the flexors and extensors of the elbow and many other muscles as well. Movements of coöperation also take place;[2] of these one may mention arm-swinging in walking.

The Abdominal Wall as a Muscle.

Turning now to the behaviour of the abdominal wall as muscle, we find its activities intimately related to other groups of muscles. We see a "great cylinder" (Keith), the sides of which are formed by the erector spinæ, quadratus lumborum, and the abdominal wall, while the top and bottom are imperfectly closed by the diaphragm and the pelvic floor. Sir Arthur Keith states: "We are apt to forget that the chief muscles of the belly wall, the two recti, the external obliques, and the internal obliques are primarily muscles of the spine; they are powerful postural antagonists of the component elements of the erector spinæ muscles. . . . The student is so apt to concentrate his attention on the respiratory action of the ribs that he forgets that they are the most powerful of the spinal levers. All the muscles attached to the ribs—the intercostals, the rectus abdominis, and oblique muscles of the belly wall—are prime movers and balancers of the spine."[1]

The abdominal wall, being antagonistic to the diaphragm, acts as a respiratory muscle; it contracts during expiration, forcing the latter up, the energy being transmitted hydrostatically. Prof. Starling wrote: "In fact, Sherrington's results on the coördination of muscular movements would tend to make us assume inhibition of the tone—e.g., of the abdominal muscles, during inspiration, and active augmentation of tone during expiration. Where the tone of the muscle is entirely lost—e.g., in the condition of visceroptosis—it has been observed that the diaphragm is thrown out of action, breathing being chiefly carried out by an elevation of the upper part of the thorax."

We must now refer to the action of the abdominal wall in a movement which may be termed "flattening out the lumbar curve," as it will be made use of during treatment. It can take place in any position, but one should realise that, unless the lumbar erector spinæ relax reciprocally, it cannot occur. During this movement the abdominal wall is normally the prime mover, but in certain positions, such as lying supine or reclining in a chair, gravity assists and, in fact, may supply the entire energy requisite for the movement, while the abdominal wall merely shortens passively. Under some conditions the movement is assisted by contraction of gluteus maximus and the hamstrings. When the action of these muscles becomes of importance, it will be seen that the movement approximates to a rotation of the pelvis, and that this rotation would, for instance, in the standing position, take place about an axis drawn through the hip-joints, whereas in other positions a variation from this axis would occur. For practical purposes this rotation, which is an important factor in treatment, may be described as "turning the tail between the legs," and it is interesting to notice the coöperation between the abdominal wall on the one hand and the gluteus maximus and hamstrings on the other. The rotation may be readily perceived by laying the hand on the sacrum, though not, however, on gluteus maximus, if this latter is strongly developed.

One further point before passing on: Should a patient maintain a contraction of the erector spinæ, make a contraction of the abdominal wall and, at the same time, hold his breath, one then observes that his chest is forced up. This combination of muscle actions frequently occurs when a patient tries to flex or to flatten the lumbar spine.

Tone.

As regards the tone of the abdominal wall, Sir Arthur Keith[1] states: "The moment we assume a sitting or a standing posture there is set going a reflex mechanism which throws the muscles of the belly wall into a state of postural tone." This, of course, refers to the normal individual who has a satisfactory abdominal wall. From earlier quotations we see that this tone depends primarily on proprioceptive impulses from the constituent muscles themselves, and should note that the alternate inhibitions and augmentations of tone reciprocally in relation to the diaphragm tend to keep the abdominal wall in a healthy state.

In one type of individual we find a slack abdominal wall associated with a marked lordosis or increase of the lumbar curve. As regards the obese variety of this type, there is, in Dr. W. F. Christie's "Surplus Fat and How to Reduce it," a clever sketch entitled, "Election Day at the Fat Man's Club." The next gentleman to enter in is depicted sideways on, displaying a magnificent "object in view," as a large tummy is sometimes called, and one notices a strongly developed lordosis. It has been found that a proportion of this type, both the obese and the thin varieties, suffer pain in the lumbar region, and often it is for this reason that they submit themselves for treatment. This pain may arise in the joints—vertebral or sacro-iliac—or else in the muscles and surrounding structures; if in the latter, it is due to the presence of waste products, to strain or to spasm required for the fixation of painful joints, and in any case a lack of coördination of the constituents of the muscle group is likely to be a factor of some importance.

Anyone who wishes to appreciate the condition of this type of patient should clasp with both arms a heavy weight, holding it about the level of the umbilicus, and walk upstairs. Balance is preserved by canting the upper part of the body backwards, maintaining this attitude by a contraction of the lumbar muscles. After mounting several flights of stairs in this way a pain in the back may become quite noticeable. When a group of muscles finds itself antagonistic to another strong group held in contraction, its tone tends to be inhibited. Such an inhibition of tone tends to be forced on the abdominal wall whenever the lumbar muscles are held in spasm. It will thus be realised that normal activity of the abdominal wall in relation to the diaphragm tends to improve the tone of the abdominal wall, whereas spasticity of the lumbar muscles tends to depress it.

Another type of individual has a thin and sagging abdominal wall, but without any undue lumbar curvature or, in fact, with a deficiency thereof. As a rule, the cervical curve is exaggerated (ewe-neck) in order to assist in giving a horizontal line of vision, the tilt of the eyes, the relation of occiput to atlas, and the dorsal curve being variables in this respect. As will be shown later, the proprioceptive messages from the prevertebral cervical muscles are an important factor in the tone of the abdominal wall. In this type of patient the abnormal balance between the post and prevertebral cervical muscles is the key to the situation.

We must refer briefly to alterations of tone of the abdominal wall due to impulses which arise in the afferent nerve-endings of the viscera. On the one hand, rigidity of the former is a well-recognised symptom of acute conditions in the latter, while on the other hand Sir C. Sherrington demonstrated that when the afferent nerves from the viscera are severed, the abdominal musculature loses its postural tone.

Posture.

"In the maintenance and recovery of posture many separate types of reflex converge to produce a common result, and these reflexes arise from such sense organs as the labryinth, the eyes, and the muscles themselves. The removal of the central hemispheres has but little effect on normal posture or on righting reactions by which that posture is resumed after having been interfered with. It is clear, therefore, that these reactions are true reflexes, and it would be quite wrong to imagine that the animal knows that its posture is being upset, resents interference, and voluntarily acts in such a manner as to counteract the offence." [4]

"Consciously, we are in complete ignorance of the specific muscular units effecting a 'voluntary' movement. . . . The point at present is that a very large part of every 'voluntary' movement is both 'involuntary' and outside consciousness." [3]

Prof. Magnus's researches have classified these reflexes in terms of the organs from which the stimuli arise, also as to whether they refer to movement (stato-kinetic) or rest (static), both as regards "pose" or "righting." "In general we can say that by means of the stato-kinetic reflexes the body is brought into its normal pose, which pose is maintained by the operation of the various static reflexes. It will have been noticed that the head plays an important part in deciding most of these responses. The head contains the organs of special sense, particularly the distance receptors for sight and sound, so that the head tends to be voluntarily directed towards stimuli which affect these sense organs. The proper orientation of the remainder of the body which ensues is effected by the action of the various reflexes which have been described." [4] Dealing with the same subject, Prof. Starling wrote: "In the evolution of the nervous system there has been a continual subordination of the hinder parts to the head end, in consequence of the development at this end of the all-important *distance receptors*, the impulses from which take a predominating part in determining the reactions of the body as a whole."

Dr. Kinnier Wilson's example of muscle action, when firmly closing the fist, may be amplified. If it took place in a standing or sitting position, the muscle action of the trunk, coördinated to maintain posture, would be synergic and also would fail to obtrude into the field of consciousness. The man would not notice the pose of his body, which would be taken up in accordance with his normal habit.

Sir Arthur Keith [1] points out that the spine of the human baby changes from the primitive curve in the second year of life, and adopts the lumbar curve. This alteration takes place through the medium of the spinal muscles—the spine's balancers. We must not consider this lumbar curve as fixed, but rather as varying continuously to suit the requirements of the moment. The same applies, and even more so, to the relative tension of the balancing muscles. One might argue that, while this curve is being established, consciousness takes it into account, but certainly later it passes unnoticed, unless commented on by a parent. The child is consciously concerned with his hand movements, &c., and only gross mis-balances of the lumbar and abdominal muscles are recognised. We thus see that it is possible for an undue contraction of the lumbar muscles to arise in early youth and develop, so to speak, along with the child; this contraction would merely be a failure to adapt the body to its environment. The so-called "pot-bellied" type of child constitutes a more serious condition than the above; the disturbance in this case is probably visceral in origin.

As a rule, it is probable that a lumbar spasm, as we now can term it, arises as a secondary condition to a mal-posture of the shoulders and dorsal region. The child gets tired either when standing or sitting; the shoulders droop and the dorsal region becomes round. The parent or teacher, thinking of the contracted chest, says "sit up," directing the child's attention to its head and also, perhaps, to its shoulders. As the levator anguli scapulæ rhomboid-serratus magnus sheet of muscle, as well as the dorsal muscles, are tired, the child compensates in the easiest possible manner, namely, by contracting the lumbar muscles and, by inducing a lumbar curve, makes the dorsal curve less apparent and the cervical lordosis (ewe-neck) less pronounced—" . . . sitting bolt-upright is particularly exhausting, especially for young people . . ." (Keith.)

When dealing with patients who have a slack abdominal wall, it is usually noticeable that, in the erect position, attempts to flatten the shoulders or decrease a dorsal curve are not limited to the correct muscles, but irradiate downwards to the lumbar area, or sometimes upwards to the cervical region. Before treatment they are virtually unable to contract alone the dorsal muscles; this is so even after the movements concerned have been performed passively to ensure they realise what is required.

Brief reference must be made to conditions that may arise subsequent to pregnancy; treatment is discussed in "A Textbook of the Practice of Medicine" (F. W. Price). It appears that the lumbar spasm—accompanied by pains in the back—which is so often a feature of the last few months of pregnancy, occurs in the effort of preserving balance when walking or standing. In some cases this postural habit persists after childbirth, although the stimulus which gave rise to it is no longer present; such conditions as tender sacro-iliac joints, if inadequately supported, would encourage this persistence. It is suggested that this lumbar spasm militates against and tends to delay the recovery of the stretched abdominal wall, the proprioceptive impulses from the former tending to reduce the tone of the latter.

Proprioceptive impulses from the neck muscles have already been mentioned as a stimulus which increases the tone in the abdominal wall. Prof. Magnus's cinematograph films of *falling cats*, which showed the head righting first, and then the body, indicate a chain reflex compounded from a labyrinthine reflex as regards the head and a neck reflex as regards the body. When *teaching* a horse a correct "reining back"—the forefeet moving first, so as to arch the spine and necessitating a full contraction of the abdominal wall—one notices the extreme importance of a correct muscle balance in the neck. When teaching patients a good neck posture they frequently, on their own initiative, draw attention to the increased tone in the abdominal wall, which accompanies their newly-acquired neck movement. This can be demonstrated both when lying and when erect; it is certainly not merely a transient stretch reflex. Unfortunately, little research seems to have been done on this point, but it *appears* certain that the neck reflex which *accompanies* a good neck carriage is an important factor in human posture.

Sir Arthur Keith draws attention to the difference between a power of voluntary contraction and a condition of postural tone. An abdominal wall may be excellent when voluntarily contracted, and yet a few minutes later, when the patient's *attention has* been directed to something else, it may revert to "C3" as regards postural tone. We can state the conclusion that a posturally slack abdominal wall is associated with either an undue lumbar spasm or a deficient tone in the prevertebral neck muscles, or with both. Healthy exercise in relation to the diaphragm helps to maintain the *abdominal wall in good condition* and delay its degeneration. Teaching relaxation of the antagonist is *the first principle* of re-education as laid down by Dr. J. B. Mennell; [5] it is undoubtedly the first step in a rational treatment of a slack abdominal wall.

Reflexes.

We find ourselves faced with a problem of postural reflexes and, in order to follow the subject to its logical conclusion, we must invoke the aid of Prof. Pavlov's researches, from which we can obtain valuable assistance. It is not easy to recognise at first sight exactly with what we are dealing; for instance, the supposed inborn reflex which Pavlov extensively employed—namely, the "salivation of animals on sight and smell of meat—is not an inborn or unconditional reflex, but an acquired one.";[4] it is probable that it is predisposition to such a reflex which is transmitted by heredity. Are we dealing with an inborn reflex *in the case of the* lumbar muscle tensions or in the case of belly wall (see previous quotation from Keith)? If so, to what extent are they inherited, and how much conditioned by the experience of the individual?

In point of fact Pavlov himself inhibited an inborn reflex by means of another one, as he records in his work "Conditioned Reflexes." As Prof. Starling stated: "It is however possible to extinguish artificially a (conditioned) reflex in the course of a few minutes. Such an experimental extinction of conditioned reflexes can be obtained by arranging the conditions of the experiment, so as to break the first law of conditioned reflexes, namely to use the conditioned stimulus several times in succession without combining it with the unconditioned stimulus." Thus the deleterious effects of either type of reflex can be got over when desirable, but we must beware of inhibiting inhibitions which we are trying to establish.

Let us take it that, at the present stage of the development of our race, the muscular contractions inducing those compensatory spinal curves which are designed to keep the head level, &c., in the most satisfactory manner, are an inherited reflex. Groups of stimuli from the labyrinth, neck, &c., that arise on the assumption of the erect position, act in relation to the above. In the normal human being the erect position evokes an *increased tone in the belly wall* (Keith). We must remember that from the assumption of the erect position there does not result just a single stimulus but a group of stimuli, some or other of which may predominate in each individual. Pavlov found that such factors as old age, pregnancy, distension of the bowels, ill-health including digestive troubles, drugs such as caffeins, bromides, alcohol, &c., altered the relative intensity of excitation and inhibition. Under these *conditions it is* simple to imagine how the normal reflex in relation to the erect-position group of stimuli becomes inhibited and at first some, then more, of these stimuli come to "condition" the increased tone of the lumbar muscles and to have a reciprocal effect on the abdominal wall, as already described.

Treatment.

The outline of treatment consists of dissociating the postural stimuli from the patient's undesirable postural motor reactions, and then linking them up with those that are more satisfactory. The patient practises on the one hand. the required muscle actions—individually or in groups—in positions in which the postural stimuli of the erect position either do not operate or are naturally inhibited. On the other hand, the same postural stimuli are allowed to act under temporal or spatial conditions, in which they do not call forth his undesirable reactions. Thirdly, the patient is shown how to encourage the linkage of stimuli with a satisfactory posture. Besides this he must appreciate from the outset how to avoid undoing the results of his efforts during the intervening periods, until the new postures become automatic when conscious effort is no longer required.

The use of stretching exercises to deal with spasticity *in the* lumbar region would not appear to produce the best results. As a rule, forcible stretching *is* not required and if it were, the patient's condition would probably lead to it being contra-*indicated*. It is far wiser to teach a relaxation and trust that such stretching as is necessary will come with improved function.

Following the lead of Pavlov's work, we see the importance of the "erect position" being really a group of conditioned stimuli instead of being a single one. A man who has just learnt to relax his lumbar muscles when sitting *in* a certain chair may not be able to repeat this under slightly different conditions—e.g., in a chair with a lower seat or back at a different slope. He certainly cannot repeat the relaxation at once when standing; *this is* important, because patients are inclined to try and estimate progress when standing up at the termination of a treatment. Pavlov shows that with dogs, stimuli from other parts of the brain effect conditioned reflexes both as regards synthesis and inhibition—with human beings this must occur to a still greater extent—thus the memory of failure or success in a movement or exercise may make a vast difference to results. In this postural work one finds that what suits one patient is virtually useless with another, although the conditions appear to be almost identical.

From the foregoing one can guess that exercises in the erect position should be given with caution at first. In "sitting" one can use from the outset certain relaxation postures and exercises, but in "standing" anything of the kind is contra-indicated, as it would tend to inhibit the inhibition we are developing. Certain uncommon positions are of extreme value, as for instance, "hands and knees"; provided the heart, &c., permit, there appears no objection to the assumption of this position, as patients over 70 years old, and others over 20 stone, have taken to it eagerly. These uncommon positions have an advantage of being a virgin field as regards stimuli; in them the stimuli have never been wrongly connected and so do not require to be inhibited. Lying positions are of the greatest importance, as is so strongly advocated by Dr. Joel E. Goldthwait.

One must say, however, that it is essential to connect what is learnt in the above positions with what one wishes to take place in "standing" or "sitting." This can be done either by a steady transition from one position to another, or by the patient grasping a similarity of joint movements, muscle actions, &c., noting the varied effect of gravity on the different parts of his body. Another useful method is to arrange that the contractions of the postural muscles are synergic to other muscles, whose activity is for the moment vividly within the field of consciousness. Synergism is thus used as a stepping-stone between voluntary effort and normal postural activity. Incidentally, in this way, a patient is led on from the idea of a correct posture, when his body is at rest, to one when he is in motion.

As Prof. Starling wrote: "The shorter the intervals between the successive presentations of the conditioned stimulus the quicker the extinction." This, of course, applies equally to the re-synthesis. "A conditioned reflex which has undergone such extinction, however, regenerates spontaneously after a few hours. . . . Repeated extinction has much more profound effect, and the spontaneous regeneration of such reflexes is progressively slower and less complete so that after having undergone several extinctions, the reflex disappears altogether."[4] Tri-weekly, or even daily, treatment in gymnasiums where patients undertake complicated exercises, difficult to repeat except under the eye or with the help of a gymnast, do not appear likely to give the optimum results. To obtain these, it seems best to visit the patient and work in his own study and/or bedroom, so as to show him exactly how to use his own chair, sofa, &c., to the best advantage. "Little and often," as Dr. J. B. Mennell points out, should be the rule; practice at decreasing intervals soon makes a posture automatic and re-establishes a good habit. One must show the patient movements and relaxation postures applicable to various occasions, those for before rising and after retiring, those for use when turning over a leaf of his paper, when strap-hanging in the tube, sitting in the car or bus, when "dummy" at bridge—no one would notice that a curative process was in progress, so there would be *no* cause for comment or laughter.

Reference has been made to relaxation postures. These are most important. As examples, one may cite: sit with one's feet on a footstool so as to avoid an undue lumbar curve; have a pillow under the knees if taking breakfast in bed; lie on one's side with the knees drawn up, especially if this is associated with "turning the tail between the legs." This tilting of the pelvis is of course one of the most valuable movements. Many patients are unable at first to contract gluteus maximus or the hamstrings to assist in the movement. In this case contraction of the specific muscle is best learnt alone—for example, when reclining against pillows in bed, straighten out the hip-joint and slide down in bed. No one, unless paralysed, &c., could fail to do this simple *movement*, and the required contraction, after having been felt, can be performed in other *positions* and in combination with that of other muscle groups.

Looking glasses are useful during treatment, as ocular demonstration has a great power of suggestion. The usual three-quarter length wall-glass and a hand, or *other* portable, mirror will suffice; they are especially valuable when teaching neck postures. Shadow*graphs* and a blackboard *have* been advocated for postural instruction.[5]

The number of *treatments* required depends largely on the voluntary control the patient has over his various muscles. An incoördinate *patient* who has never been accustomed to games of skill will take longer, especially if he has extreme weakness of the abdominal wall and spasticity in the *lumbar* region, than one who has to some degree trained for sport or athletics. Additional disturbances, such as round shoulders, a contracted chest, *especially* in elderly people, increase the difficulty of obtaining a satisfactory result and, consequently, the length of treatment. Sometimes *it* is found that even a couple of treatments suffice to put a man on the *right* road so that he can continue to develop good habits by himself. It is taken for granted that during a treatment of the nature described in these notes, the medical practitioner in charge of the case will prescribe such medicinal or other treatment as he deems advisable. One must add, in conclusion, that the feeling of well-being that comes from an improvement in portal circulation and greater activity of the abdominal wall is sufficient incentive for a patient to continue the slight amount of effort that is needed.

I am permitted by Sir Arthur Keith to say that, in his opinion, facts are brought to light in this communication which would be useful in practical therapeutics, and which, while well known to workers along the special line, are not necessarily equally well known to practitioners. This has encouraged me to publish the notes.

NAVAL TRAINING ASHORE.

THE good training ship, H.M.S. *St. Vincent* (Portsmouth), seems like Antæus to have gained fresh vitality since it touched mother earth and took over the old Marine Barracks at Gosport. Surgeon-Commander H. W. Nicholls tells in the *Journal of the Royal Naval Medical Service* for July of the comfort and care which surround these bluejacket boys, of whom there are at present about 600. During a nine months' stay a boy adds on the average 8 or 9 lb. to his weight and 2 to 3 inches to his height. The boys are housed in four blocks, with a separate building for new entries. Heating is by radiators throughout; in winter dormitories are warmed up from 2 A.M. until the boys have finished dressing and fires are lighted early in the school rooms for the work which is done there before breakfast, Commander Nicholls believing these early hours to be the danger period. Special attention is given to providing green vegetables which he finds discourage boils. The routine baths are hot and cold showers, and are fully used, voluntarily, too, after games. Physical training, in which games play a large part, produces remarkable results; the boys take quickly to hockey and Rugby football, but some prefer reading, and there is no compulsion. There is a covered swimming bath. Among new entries there were seven cases of mumps, four of scarlet fever, in nine months; apparently none among "old boys." There are 26 beds in the sick bay; work in the ship is strenuous, and the common form of "going sick" is a tiredness which is slept off in 24 hours, duty being resumed in 48. Recruits are coming in more from Gosport now, where parents see how well off the boys are. The medical officer notes with admiration their ability to eat a two-course dinner in seven minutes, without ever a complaint of indigestion. It is pleasant to know that another wooden training ship, with its risk of infection from confined space, has been disestablished. Ut exeant omnes!

IS THERE A NEUROTROPIC SPIROCHÆTE?

MANY of the reports on acquired syphilis in family groups emphasise the frequency of neurological complications, and invoke the influence of a so-called neurotropic strain of *Spirochæta pallida*. H. Noguchi and other workers distinguished this strain from the "dermatropic" by its size and variations in its incubation characteristics in experimental animals, as well as by its results. There is a school of thought which holds that infection from a common source tends to produce the same type of syphilis in all who catch it. A number of investigators, however, believe that the soil is more important than the parasite in determining the form of the manifestation. The former produce evidence of the disease, taking the same form in husband and wife; J. E. Moore and A. Keidel studied 111 married couples and found that in 57 per cent. of the cases with parenchymatous neurosyphilis the partner also had neurosyphilis in some form. A similar experiment at the Mayo Clinic, however, only yielded 22 per cent. of positive results.

In order to see what evidence could be produced on the other side, that of the predominance of family characteristics, Dr. P. A. O'Leary and Dr. M. W. Rubenstein have investigated[1] 13 families whose members had acquired syphilis from different sources. They eliminated patients with any signs of congenital syphilis or parental history before the birth of children, and exacted clinical and serological evidence of syphilis, and a history of chancre followed by secondary signs. There were four groups of sisters, two of brothers, two of brother and sister, two of mother and son, two of mother and daughter, one of father and son, and one of mother, son, and daughter. In seven families more than one member, in two neither member, and in four families one member only had neurosyphilis.

Although these observers agree that trauma, disease, virulence of the organism, and the type of treatment are important factors, they see in their results evidence for the greater importance of the family characteristics. The results of treatment gave a more striking indication of the working of this factor, for in five out of the seven families with neurosyphilis all the members responded favourably, while in the other two none responded. The conclusion seems to be a sensible one, but the smallness of the number investigated throws doubt on the evidential value of the experiment.

NEW PREPARATIONS.

Eukodal.—This analgesic preparation, supplied by H. R. Napp, Ltd., 3 and 4, Clements Inn, Kingsway, London, is introduced as an ideal substitute for morphine. Codein is not held to be dangerous as an addiction drug, and has been excluded from the Dangerous Drug Act. The formula is given as dihydroxy-codeinon hydrochloride, and it is claimed both to be an excellent substitute for morphine and of great value when used in conjunction with morphine. The narcotic and analgesic effects are produced when the drug is administered orally, where its employment is specially recommended for allaying irritative cough, while to meet cases of pain subcutaneous injections may be employed.

The same firm sends us a new theobromine preparation, *Theosol*, whose full formula is theobromine calcium salicylate, a formula which explains the intentions which have led to the preparation of the drug. The indications for its use are probably familiar to many of our readers; this combination has been recognised of value in arterio-sclerosis and asthma of the cardiac form, and is also found to possess diuretic qualities.

LONGEVITY.

THE *Times*, on August 13th, devoted a leading article to Mr. Li Ching Yun, who is alleged just to have celebrated his 250th birthday, the representative of the *North China Herald* having visited him and found him quite well. His name is at any rate worth putting on record, as Thomas Parr with his 153 years is put completely in the shade. Some people are doubtful of Parr's credentials, but in December, 1926, the death was reported at Constantinople of Zaro Agha at the age of 153, and mention was made then of Teku Oglu Ali Agha, aged 147. In November of that year, also, the death was reported, at the age of 135, of Maria Ustav, in Carcaliu, Tulcea, Dobruja, Roumania, who lived on vegetables and fish and was a strict teetotaller, but no doubt consumed the soured milk of the country to which the number of centenarians in Bulgaria and Roumania is largely attributed. It is presumed, of course, that the Chinaman has not been celebrating his birthday every six months.

INADVERTENCE.

IN reply to natural expostulation we admit that the advertisement wherein an impossible virtue was claimed for a particular ointment was inserted without due attention to its contents. We much regret the inadvertence.

STUDENTS' GUIDE—SESSION 1928-1929.

GENERAL COUNCIL OF MEDICAL EDUCATION AND REGISTRATION OF THE UNITED KINGDOM.

POWERS, DUTIES, AND CONSTITUTION.

The General Council of Medical Education and Registration of the United Kingdom is, first, a registering body: no person, even though his qualifications have been obtained by examination, is a *legally qualified* medical practitioner until his name appears on the Medical Register. Secondly, it is a standardising body, ensuring that medical education reaches an efficient minimum standard by scientific examination. Thirdly, it is a penal and disciplinary body, having power to remove from the Register any practitioner convicted of felony or misdemeanour or adjudged guilty of professional misconduct. Fourthly, to the Council is committed the codification of pharmaceutical remedies. The duties of the Council are thus primarily of a public nature, and its construction shows its fitness for its fourfold responsibilities.

The Council consists of 38 members, of whom all but 11 are official representatives of some corporate body. Five members are chosen by the Crown on the advice of the Privy Council, and six others are elected by the members of the medical profession as Direct Representatives. The Crown members need not be medical men and one layman now sits on the Council. Three members are appointed for dental business by the Privy Council under the Dentists Act, 1921, under which the powers and duties of the General Medical Council with regard to the keeping of the Dentists Register and the administration of the Dentists Acts were largely transferred to the Dental Board of the United Kingdom.

The Educational Curriculum.

Professional Education.—The course of professional study after registration as a student occupies at least five years. The Final Examination in Medicine, Surgery, and Midwifery must not be passed before the close of the fifth academic year of medical study.

Regulations as to Registration of Medical Students.

Before registration as a student every candidate should produce evidence that (*a*) he has attained the age of 17 years; (*b*) that he has passed a recognised examination in general education; and (*c*) that, *in addition thereto*, he has passed, or obtained exemption from, an examination, theoretical and practical, in elementary physics and elementary chemistry conducted or recognised by a licensing body. The minimum standard of General Education required is that of University Matriculation or entrance examination in the Faculties of Arts or Pure Science. In other Faculties the examination must be of the standard prescribed in Regulation 2 below.

An approved course of instruction in elementary biology at a secondary school or other teaching institution recognised by a licensing body may admit a student to the professional examination in elementary biology upon registration as a medical student.

The candidate commencing medical study should apply to the registrar of the division of Great Britain and Ireland in which he is residing, according to a prescribed form, copies of which may be had on application to the several licensing bodies, medical schools, and hospitals, or at the offices of the Council; and should produce proof that he, or she, has fulfilled the first three conditions.

The Maintenance of the Register of Medical Students.

1. The Education Committee prepares and issues from time to time a list of examining bodies whose examinations in general education fulfil the conditions of, and are specially recognised by, the Council.

2. The Council has recognised the undernoted university examinations which are conducted in Great Britain and admit to the Faculties of Arts or Pure Science, or to other Faculties, subject to the conditions specified below:—

Oxford University, Responsions; Cambridge University, The Previous Examination. The Matriculation Examinations of the following Universities: Birmingham, Bristol, Durham, Leeds, Liverpool, London, Victoria of Manchester, Sheffield and Wales, and the Entrance or Preliminary Examination of the Universities of Scotland.

The condition prescribed by the Council in Faculties other than Arts or Pure Science is that:—

The certificate shall bear evidence that the candidate has passed in the Matriculation or Entrance standard, in the following subjects, viz.: (*a*) English. (*b*) Mathematics, Elementary. (*c*) A language other than English. (*d*) A fourth subject, as defined in the regulations of the particular Examination, to be chosen from the subjoined list, viz.: History, Geography, Physical Science, Natural Science; Latin, Greek, Hebrew, French, German, or other language accepted by the University for the purpose of matriculation or entrance.

3. Subject to the condition prescribed above (Section 2), the Council will recognise those of the examinations conducted by recognised authorities in Great Britain which are accepted by any one or more of the above-named Universities as equivalent (under prescribed conditions as to "credits" or "grades"), for purposes of Entrance or Matriculation, to an Examination named in the preceding list (Section 2). Such Examinations are:—

Bristol University: Higher School Certificate Examination; School Certificate Examination. Cambridge Local Examinations Syndicate: Higher School Certificate Examination; School Certificate Examination. Central Welsh Examination Board: Higher Certificate Examination; School Certificate Examination. Durham University: Higher Certificate Examination; School Certificate Examination. London University: Higher School Certificate Examination; General School Examination. Northern Universities Joint Matriculation Board: Higher Certificate Examination School Certificate Examination. Oxford and Cambridge Schools Examination Board: Higher Certificate Examination; School Certificate Examination. Oxford Delegacy for Local Examinations: Higher School Certificate Examination; School Certificate Examination. Scottish Education Department: Leaving Certificate Examination.

4. The Council will continue to recognise certain Examinations conducted by Educational Bodies, other than those (mentioned in Section 3) whose Examinations are accepted by any one or more of the Universities of Great Britain. Recognition will not be extended under this Section to any Examination unless the Council is satisfied (*a*) that in scope and standard it is equivalent to a recognised Matriculation or Entrance Examination of a University of Great Britain, (*b*) that it fulfils the condition prescribed by the Council (Section 2), and (c) that the Examination has been completed at not more than two sittings. Such Examinations are:—

The College of Preceptors (England): Senior Certificate. The Educational Institute of Scotland: Preliminary Medical Certificate.

5. Subject to the prescribed condition (Section 2), the Council will recognise the Entrance Examination to the School of Physic of the University of Dublin, and the Matriculation or Entrance Examinations of the National University of Ireland, the Queen's University of Belfast, the Irish Royal Colleges of Physicians and Surgeons: and also the Leaving Certificate of the Department of Education of the Irish Free State, the Senior Grade Leaving

Certificate of the Ministry of Education of Northern Ireland, and all examinations accepted by any one or more of the Universities of Great Britain or Ireland. as equivalent, for purposes of entrance or matriculation, to the above-named University Examinations.

6. Subject to the prescribed condition (Section 2), the Council will recognise all Examinations of Colonial or Foreign Universities which are accepted by any one or more of the Universities of Great Britain as equivalent, for purposes of entrance or matriculation, to an examination named in the list of examinations recognised by the Council (Section 2).

7. The Council will recognise the Final Examinations for Degrees in Arts or Science of any University of Great Britain or Ireland or of the British Dominions.

8. The registration of medical students shall be placed under the charge of the Branch Registrars.

9. Each of the Branch Registrars shall keep a register of medical students.

10. The Branch Registrar shall enter the student's name and particulars in the Students Register, and give him a certificate of such registration.

11. Each of the Branch Registrars shall supply to the several licensing bodies, medical schools, and hospitals, in that part of Great Britain or Ireland of which he is Registrar, blank forms of application for the registration of medical students.

12. A copy of the Medical Students Register prepared by each of the Branch Registrars shall be transmitted, on or before Dec. 31st in each year, to the Registrar of the General Council, who will distribute the list to the licensing bodies, medical schools, and hospitals.

All applications for special exceptions to the foregoing regulations as to registration shall be addressed to the Registrar of the General Council, and shall be decided by authority of the Education Committee, who shall report thereon to the Council.

The Medical Schools and Colleges.

The Universities, including their Colleges and Medical Schools, and Schools of Medicine at which Medical Study may be commenced in the United Kingdom are set out seriatim in the following pages.

MEDICAL REGISTRATION IN IRELAND.

Within the past few months the problem of medical registration in the Irish Free State, which had given rise to some anxiety during the past two years, has been satisfactorily settled. By agreement between the Governments of Great Britain, of the Irish Free State, and of Northern Ireland—since confirmed by legislature at Westminster and Dublin—the powers and duties of the General Council of Medical Registration and Education are to continue as heretofore in respect of qualifying bodies in the Irish Free State, and of medical practitioners qualified in the Irish Free State. Side by side with this a Medical Council has been set up in the Irish Free State with the duty of establishing and controlling a Register for the Irish Free State. Practitioners whose names are on the General Register, and persons who pass a qualifying examination in the Irish Free State, will be registered on the Irish Free State Register on payment of the prescribed fee. The Irish Free State Medical Council have, over those whose names are on the Irish Free State Register, the same disciplinary powers as are possessed by the General Council over those whose names are on the General Register. To possess the privileges of a qualified practitioner in the Irish Free State it is necessary to be registered in the Irish Free State Register.

The net result of the change in the law as regards the practitioner qualifying in the Irish Free State in the future is that: (1) If he intends to practise only in the Irish Free State he need only register in the Irish Free State Register; (2) if he intends to practise in Great Britain he will register in the General Register: and (3) if he is in doubt where he will practise he will register in both Registers. He will, as he registers in one Register, or in both Registers. put himself under the disciplinary control of the one Council or of both Councils. No practical inconvenience is caused, and practitioners qualified in the Irish Free State in future will not find themselves deprived of any of the privileges or rights enjoyed by their predecessors.

THE DENTAL BOARD OF THE UNITED KINGDOM.

Anyone who is on the Medical Register is entitled to practise as a dentist, although he cannot register as such without degree or licence in dentistry; but it is a distinct advantage to take a special dental qualification, otherwise few dental appointments at general or special hospitals or dispensaries are available, and, unless registered in the Dentists Register, no dental work, under the additional Benefit Scheme of the National Health Insurance Act can be undertaken.

Under the Dentists Act, 1921, the powers and duties of the General Medical Council under the Dentists Act, 1878, and under the Medical Act, 1886, which related to the keeping of the Dentists Register and the administration of the Dentists Acts were largely transferred to the then newly constituted Dental Board of the United Kingdom. The registration of dental students at the commencement of their dental studies, and the right of erasure of a name from the Dentists Register, remain with the Council, but the duty of inquiring into disciplinary cases rests with the Board, upon whose recommendations the Council acts.

The Dental Board consists of a chairman and 12 members. The chairman is appointed by the Privy Council. Other members of the Board are appointed by the Minister of Health, the Scottish Board of Health, the Governor-General of Northern Ireland, the General Medical Council (3), Direct Vote of the qualified dentists practising in England and Wales, Scotland, and Ireland (3), Direct Representatives by registered dentists not being qualified dentists (2).

Registration of Dental Students.

The General Medical Council's Regulations in regard to the registration of dental students which came into force on Jan. 1st, 1923, provide that the registration of dental students shall be carried on at the General Medical Council Office in London, in the same manner as that of medical students, and be subject to the same regulations as regards age and preliminary examinations; but in the case of dental students professional study may commence either at a recognised dental hospital or school, or by pupilage with a registered dental practitioner.

Candidates for a diploma in dental surgery should produce certificates of having been engaged for at least four years in professional studies, and of having received during 24 calendar months instruction in dental mechanics. It is recommended that instruction in dental mechanics be taken at a recognised dental hospital and school. If any part of such instruction be taken by the candidate as a pupil with a registered dental practitioner, the time required to be devoted to it shall be at least twice the time required for the corresponding instruction taken at a dental school. Two years' *bona-fide* apprenticeship with a registered dental practitioner, after registration as a dental student, may be counted as one of the four years of professional study. When a student can show evidence of regular pupilage in dental mechanics to a registered dental practitioner, prior to the passing of the prescribed preliminary and scientific examinations, he may be allowed to antedate his registration for a period not exceeding one year prior to the passing of these examinations.

THE OFFICES.

The address of the Registrar, to whom further communications should be addressed, is as follows: The Registrar of the General Medical Council, 44, Hallam-street, Portland-place, London, W. 1. The offices of the Dental Board are adjoining.

A memorandum on the procedure to be adopted by those who desire to enter the profession of medicine, with notes on costs and prospects, and a similar Memorandum in regard to Dentistry, may be obtained on payment of 1*s*. each.

THE MEDICAL EXAMINING BODIES AND SCHOOLS OF THE UNITED KINGDOM.

A GUIDE TO THE FACILITIES FOR OBTAINING THE VARIOUS MEDICAL DEGREES AND OTHER QUALIFICATIONS FOR THE BRITISH MEDICAL REGISTER.

I.—ENGLAND AND WALES.

THE UNIVERSITIES.

UNIVERSITY OF OXFORD.

THERE are two degrees in Medicine, *B.M.* and *D.M.*, two in Surgery, *B.Ch.* and *M.Ch.*, and diplomas in *Public Health* and *Ophthalmology*. The examinations are open to men and women alike.

Only Graduates in Arts of the University are eligible for the Medical and Surgical degrees. The most convenient course for the B.A. degree for intending graduates in Medicine is to take Responsions, the *Preliminary Science* Examinations mentioned below, and the Final Honour School of Physiology. To obtain the degrees of B.M. and B.Ch. the following examinations must be passed: 1. Preliminary subjects: Physics and Chemistry, Zoology, and Botany. 2. Professional. (*a*) First Examination: Subjects—Organic Chemistry, unless the *candidate* has satisfied the examiners in Part I. Chemistry in the Honour School of Natural Science; Human Physiology, unless he has obtained a First or Second Class in Animal Physiology in the Honour School of Natural Science; Human Anatomy. (*b*) Second Examination: Subjects—Medicine, Surgery, Midwifery, Pathology, Forensic Medicine with Hygiene, Materia Medica and Pharmacology. The First and Second Professional examinations are held in June and December. The first B.M. examination may be passed at any time after the Preliminary Scientific examinations. Anatomy and Physiology must be passed at the same time—Organic Chemistry may be taken separately.

At any time after passing *First B.M. Examination*, the candidate can, on producing certificates, present himself for examination in the subjects of Pathology, Forensic Medicine with Hygiene, Materia Medica and Pharmacology; but cannot, unless he is already a registered medical practitioner, enter for examination in Medicine, Surgery and Midwifery until the eighteenth term from his matriculation, nor until a period of at least thirty-three months has elapsed from the date of passing the First B.M. Examination. He must pass in Medicine, Surgery and Midwifery at one and the same time.

Before admission to the Examinations in Pathology and Bacteriology, and Materia Medica and Pharmacology, of the *Second B.M. Examination*, the student must produce certificates of having attended courses of instruction including practical work in Pathology, Bacteriology, Post-mortem Clerking, Pharmacology, and Pharmacy, either in Oxford or in a recognised Medical School. Before admission to the remainder of the second B.M. Examination, he must produce a number of other certificates, including certificates of having acted as Clinical Clerk and Dresser, each for six months in the Wards, of instruction in Midwifery and of attendance on Labours, of instruction in Infectious Diseases and in Ophthalmology, of proficiency in Vaccination and in the administration of Anæsthetics, and of three academic years of hospital practice.

The degree of Bachelor of Surgery (B.Ch.) is granted with that of B.M. after passing the above examinations.

The degree of Doctor of Medicine (D.M.) is granted to Bachelors of Medicine of the University who have entered upon their thirtieth term from Matriculation, and have submitted a dissertation which is approved by the examiners for the B.M. degree whose subjects are dealt with therein and by Professors in the Faculty of Medicine. The degree of Master of Surgery (M.Ch.) is granted after examination to Bachelors of Surgery who have entered upon their twenty-first term, and who are members of the surgical staff of a recognised hospital, or have acted as dresser or house surgeon in such a hospital for a *period of six months*. The examination, which includes Surgery, Surgical Anatomy and Pathology and Surgical Operations, is held annually in June, after the Second B.M. examination.

The examinations for the Diploma in Public Health in two parts are held in Trinity and Michaelmas terms; that for the Diploma in Ophthalmology is held annually in July. (See p. 421.)

Travelling Fellowship, Scholarships, and Prizes.—A Radcliffe Travelling Fellowship is awarded annually after an examination held in February. It is tenable for two years and of the annual value of £300. The examination is in Physiology, Pathology, and Hygiene, and is partly "practical." Candidates must be graduates in Medicine of the University. The holder must travel abroad for the purpose of medical study. Application should be made to the Radcliffe Examiners, Department of Medicine, University Museum. A Christopher Welch Scholarship of £100, tenable for four years, is awarded annually after examination. Candidates must be men undergraduate members of the University, who have not exceeded the twelfth term from their matriculation, or been admitted to any degree in the University. They may offer any one of the subjects, Animal Physiology, Botany, Zoology. A George Herbert Hunt Travelling Scholarship of the value of about £100 is awarded every second year to enable a Bachelor of Medicine to undertake three months' study abroad. A Rolleston Memorial Prize is awarded once in two years to members of the Universities of Oxford and Cambridge of not more than ten years' standing for an original research in some Biological subject, including Physiology or Pathology. The Radcliffe Prize, founded by University College (1907), is of the value of £50 and is awarded biennially (alternating with the Rolleston Memorial Prize) for research in some branch of medical science. The Theodore Williams Scholarships, each of the value of £50 a year for two years, are awarded annually in the subjects of Anatomy, Physiology, and Pathology. A Radcliffe Scholarship in Pharmacology, of the value of £50 for one year, is awarded annually by the Master and Fellows of University College. A King's College Hospital Burney Yeo Scholarship of £80 is awarded each year on the nomination of the Regius Professor of Medicine. The Scholarships and Exhibitions in Science which are offered by most Colleges are open to those who intend to pursue Medicine. The value of these scholarships varies, according to the Candidate's need, between £30 and £100 a year; the exhibitions vary in value from £30 to £100 per annum. The *number* of scholarships and exhibitions in Science offered annually is about forty. There are also Medical Scholarships of the value of £100 a year at University College and at Pembroke College. The Welsh Memorial Prize for Anatomical drawing is awarded annually, and is of the value of about £10.

More detailed information may be obtained from the University Calendar; *from the* Examination Statutes, 1923; from the Regius Professor of Medicine; from the Professors in the departments of medical science; and from the Dean of the Medical School, Oxford.

UNIVERSITY OF OXFORD: RADCLIFFE INFIRMARY AND COUNTY HOSPITAL.—225 beds. Courses of instruction are given in connexion with the Oxford University Medical School. These include (1) a course in Practical Medicine by the Regius Professor of Medicine; (2) clinical lectures by the *Litchfield*

Lecturers in Medicine and Surgery; and (3) tutorial instruction and demonstrations in special Regional Anatomy (medical and surgical), methods of Medical and Surgical Diagnosis, and Surgical Manipulation. (4) Pathological demonstrations and instruction in post-mortem work are given by the Assistant Pathologist. Opportunities are offered to students who wish to act as surgical dressers and clerks. A post-graduate course is held in the hospital in the autumn of each year.

UNIVERSITY OF CAMBRIDGE.

There are two degrees in Medicine, *M.B.* and *M.D.*, two in Surgery, *B.Chir.* and *M.Chir.*, and Diplomas in *Public Health and Hygiene*, *Tropical Medicine* and *Hygiene*, and *Medical Radiology and Electrology.* Increased facilities have been given to women students at Girton and Newnham, who are admitted to the *M.B.* Examinations.

The student must enter a College, or become a non-collegiate student, and keep nine terms (three years) by residence. He must pass the Previous Examination of the University before he comes into residence or therefrom obtain exemption, particulars of which may be obtained from the Registrar. He may then devote himself to medical study in the University. Or he may, as nearly all students now do, proceed to take a degree in Arts by passing the Examinations for the Ordinary B.A. degree, or an Honours degree by passing a Tripos Examination. The Natural Sciences Tripos is taken most frequently by medical students, as some of the subjects are practically the same as those for the First and Second M.B. examinations.

For the degree of Bachelor of Medicine (*M.B.*) five calendar years of medical study are required either in Cambridge or at one of the recognised Schools of Medicine. The first three or four years are usually spent in Cambridge till the student has passed the examination for Part I. of the Natural Sciences Tripos and the *First and Second M.B. examinations.* Hospital practice may be attended in Cambridge, but until the student has completed the course for the *Third part of the Second M.B.* it cannot count towards the two and a half years of hospital practice required before admission to the first part of the Third M.B. The laboratories for Botany, Chemistry, Physics, Biology, Zoology, Human Anatomy, Physiology, Biochemistry, Pathology, Bacteriology, Pharmacology, Psychology, and Public Health are well equipped. Addenbrooke's Hospital, the Infectious Diseases Hospital, the Cambridge Research Hospital, and the Field Laboratories are utilised for study and research.

There are three examinations for M.B. The *First* includes (1) General and Inorganic Chemistry, (2) Mechanics, (3) Physics, and (4) Elementary Biology. These parts may be taken together or separately. The *Second* is divided into three parts—viz. (1) Organic Chemistry, (2) Human Anatomy and Physiology, and (3) Pharmacology and General Pathology. The *Third* is divided into two parts: (1) Principles and Practice of Surgery (including Special Pathology and Midwifery and Diseases Peculiar to Women); and (2) Principles and Practice of Physic (including Diseases of Children, Mental Diseases, Medical Jurisprudence), Pathology (including Hygiene and Preventive Medicine), and Pharmacology (including Therapeutics and Toxicology). The examinations are partly in writing, partly oral, and partly practical, in the hospital, in the dissecting room, and in the laboratories. An Act has then to be kept by the candidate reading an original dissertation composed by himself and being examined orally on some subject approved by the Regius Professor of Physic. Candidates who have passed both parts of the Third M.B. examination are admitted to the registrable degree of Bachelor of Surgery (B.Chir.) without separate examination and without keeping an Act.

The degree of Doctor of Medicine (M.D.) may be taken three years after that of M.B. or four years after that of M.A. The candidate is required to produce certificates of having been engaged in Medical Study for five calendar years, and if an M.A. to pass the same examinations as are required for the degree of M.B. An Act has to be kept, consisting of an original Thesis with *viva voce* examination; and a short extempore essay has to be written on a topic taken from the general subject of his thesis, whether it be Physiology, Pathology, Pharmacology, the Practice of Medicine, State Medicine, or the History of Medicine.

Candidates for the Degree of Master of Surgery (M.Chir.) who are M.A.'s may be admitted to the examination after they have become legally qualified under the *Medical Acts* to practise surgery. Others may be admitted to the examination when two years at least have elapsed after they have completed all that is required of candidates for the Degree of B.Chir. He is required to pass an examination in Principles and Practice of Surgery, Surgical Anatomy and Surgical Operations, and Pathology, and to write an extempore essay on a Surgical Subject.

Diplomas are granted in Public Health, in Hygiene, in Tropical Medicine and Hygiene, and in Medical Radiology and Electrology. Candidates must hold a recognised medical qualification. (See p. 421.)

Scholarships and Prizes.—Medical studies are endowed by the numerous Natural Science scholarships at the various colleges, information about which can be obtained from the respective Tutors. There are Natural Science scholarships at most of the colleges and prizes in the ancillary medical subjects. Some of these are entrance scholarships; some may be gained by students already in residence, and where suitable candidates are not forthcoming among such students the emoluments may be allotted to members of other colleges. A valuable scholarship instituted on behalf of Medicine is the Tancred Studentship in Physic, tenable at Gonville and Caius College. The successful candidate must enter at the college within a month or remove there if he be a member of any other college. Students are required to take the degree of M.B. as soon as they are of sufficient standing but may hold the Studentship for a further three years. Thus a student elected previous to admission to college can draw the emolument, the annual value of which is about £90, for eight years. Full particulars can be obtained from Mr. E. T. Gurdon, 28, Lincoln's Inn-fields, London. Among other scholarships and prizes may be mentioned the Balfour Studentship, for research in Biology, of the value of £300 a year for three years, not restricted to members of the University; the Frank Smart Studentship and Prizes for Botany and Zoology, and the Shuttleworth Studentship for Zoology or Physiology tenable at Gonville and Caius College. The one University Prize in Medicine, the Raymond Horton Smith Prize, is awarded to that candidate for the degree of M.D. who presents the best thesis for the degree during the academical year, provided that he has taken honours in a Tripos Examination.

An abstract of the Regulations and Schedules of the range of the examinations in Chemistry, Mechanics, Physics, Biology, Pharmacology, and General Pathology may be obtained upon application to the Registrary, The Registry, Cambridge.

ADDENBROOKE'S HOSPITAL.—100 beds. Clinical Lectures in Medicine and Surgery, in connexion with Cambridge University Medical School, are given at this hospital twice a week during the academical year; and practical instruction in Medicine and Surgery is given in the wards and out-patients' rooms by the physicians and surgeons daily during the term time and vacations. The fee for pupilship is 3 guineas a term, 9 guineas a year, 12 guineas perpetual. Further information may be obtained from Dr. Aldren Wright.

UNIVERSITY OF LONDON.

The University of London in 1900 was reconstituted under the Act of Parliament, 1898, and became a teaching as well as an examining body. Under the developments upon the Internal side all the metropolitan medical schools became constituent colleges, while Clinical Units have been established at St. Bartholomew's, the London, St. Mary's, St. Thomas's, University College Hospital, and the Royal Free Hospital.

Internal and External Students.—All the examinations of this University are open to men and women alike. Matriculated students of the University may be either internal or external. Internal students of the University are students who have matriculated at the University and who are pursuing a course of study approved by the University, either (*a*) under the direct control of the University or a committee appointed thereby; or (*b*) under one or more of the appointed or recognised teachers of the University. Centres for preliminary and intermediate medical studies have been established by the University at University and King's Colleges.

UNIVERSITY COLLEGE.—University College has been constituted a University centre for the teaching of medical sciences. The College Faculty of Medical Sciences comprises the Departments of Physics, Chemistry, Botany, and Zoology (the Preliminary Medical Sciences); also the Departments of Anatomy, Histology, Physiology, Biochemistry, and Pharmacology (the Intermediate Medical Sciences), and the Department of Hygiene and Public Health. Research work is undertaken in all departments. The completion of the Institute of Medical Sciences, which the generosity of the Rockefeller Foundation made possible, provides exceptional facilities for research and post-graduate study in anatomy, physiology, and pharmacology. In particular might be specified the opportunities for investigation in human and comparative embryology and neurology, in histology, radiology, anthropology, biochemistry, and experimental physiology and experimental embryology. Arrangements exist for the close correlation of work in the Institute with University College Hospital and Medical School. Women students are admitted.

Scholarships and Prizes.—The first four items on the present list require a complete intermediate course at University College. The money value and subjects at examinations are as follows: (*a*) The Bucknill Scholarship, 160 guineas; (*b*) *and* (*c*) two Entrance Exhibitions, 55 guineas each, Chemistry, Physics, Botany, and Zoology; (*d*) Entrance Scholarship, £30 a year for three years; (*e*) Cluff *Memorial* Prize, £15 biennially, Anatomy, Physiology, Pharmacology, and Chemistry; (*f*) Schafer Prize in Physiology, £18 triennially; (*g*) Sharpey Physiological Scholarship, £115, Biological Sciences; (*h*) Morris Bursary for sons of deceased professional men, by *nomination*, tenable for two years, £16 a year; and (*i*) five Gold and five Silver Medals awarded annually in various departments. For further information apply to the Dean of the Medical Faculty, University College, W.C.

KING'S COLLEGE.—The Medical Faculty at this College gives instruction in the subjects of Medical Science for the Preliminary and Intermediate Examinations in Medicine and Surgery, and Dental Surgery, of the University of London and of other Universities and examining bodies, to students entering the College directly, and also to students of the following four hospital schools which prepare only for the final examinations—viz., King's College Hospital, Westminster Hospital, St. George's Hospital, and Charing Cross Hospital. The Faculty is open to both men and women.

Scholarships and Prizes.—Two Warneford Entrance Scholarships of £30 each for four years. Examination in April, subjects selected from Divinity, Classics, Science. Sambrooke Scholarship of £30 for three years. Examination in April, subjects selected from Classics, Science. Worsley Scholarships: £100 in five annual instalments of £20. *At the end of the First Year* of study, the Rabbeth Scholarships (£30 and £15), the Carter Gold Medal and Prize in Botany, and the Hare Prize in Zoology are open for competition. *At the end of the Second Year*, the Second Year's Scholarship (£20) is open for competition. *At the end of the Third Year*, the Hughes Prize in Anatomy, the Huxley Prize in Physiology, the Inchley Prize in Pharmacology, and the Jelf Medal are open for competition. The Layton and the Berridge Research Studentships (£150 per annum each), the Daniell Scholarship in Chemistry (£40), Warneford Prizes (£25 and £15), Leathes Prize, Barry Prize, &c., are also open to Students of this Faculty. The majority of the Scholarships and Prizes are open to Regular Students only. For further information apply to the Dean of the Medical Faculty.

Medical students of the University of London, who are pursuing their medical curriculum in the metropolis will proceed to one of the recognised medical schools connected with the University. At four of these schools the preliminary studies will be taken at King's College, while at the other schools the whole curriculum can be taken out in connexion with the selected hospital. These hospitals are St. Bartholomew's Hospital, Charing Cross Hospital, St. George's Hospital, Guy's Hospital, King's College Hospital, the London Hospital, St. Mary's Hospital, the Middlesex Hospital, St. Thomas's Hospital, University College Hospital, Westminster Hospital, and the London (Royal Free Hospital) School of Medicine for Women. Various schools and hospitals are also recognised as schools of the University in special departments, and students may pursue their studies at other approved universities and medical schools, presenting themselves for examination at the University.

Faculty of Medicine.

The Faculty of Medicine of the University grants the joint degrees of M.B., B.S. (*Bachelor of Medicine and Surgery*), the higher separate degrees of M.D. (*Doctor of Medicine*) and M.S. (*Master of Surgery*), and the degree of B.D.S. (*Bachelor of Dental Surgery*) and the degree of B.Pharm. (*Bachelor of Pharmacy*); the two higher degrees being open only to candidates holding the M.B., B.S degrees of the University. The curriculum for the M.B., B.S. degrees is five and a half years from the time of matriculation, with certain exceptions which must be looked for in the official regulations of the University.

A. *Internal Students.*—For the Bachelor's degrees in Medicine and Surgery a student must normally, *after* registration as an internal student, have: (1) Attended prescribed courses of study for five and a half years in one or more schools of the University. (2) Passed the following examinations, under the conditions mentioned below: (*a*) The First Examination for Medical Degrees in Inorganic Chemistry, Physics, including Mechanics, and General Biology; (*b*) the Second Examination for Medical Degrees: Part I., Organic Chemistry; Part II., Anatomy, Physiology, and Pharmacology; (*c*) the Third Examination for Medical Degrees, or M.B., B.S. Examination in Medicine, Surgery, Obstetrics and Gynæcology, Pathology, Forensic Medicine, and Hygiene.

B. *External Students.*—For the Bachelor's degrees in Medicine and Surgery an external student must (1) have passed the Matriculation examination or have been exempted therefrom under Statute 116 not less than five and a half years previously; (2) have passed subsequent examinations similar to those required of an internal student; and (3) have been engaged in professional studies during the five and a half years subsequently to *Matriculation* and four and a half years subsequently to passing the First Examination for Medical Degrees at one or more of the medical institutions or schools recognised by this University for the purpose, one year at least of the four and a half years to have been spent in one or more recognised institutions or schools in the United Kingdom.

The First Examination for Medical Degrees (*Inorganic Chemistry, Physics, including Mechanics, and General Biology*) will take place twice in each year, commencing on the Monday following Dec. 7th and on the first Monday in July. It must be passed not less than nine months after matriculation.

The Second Examination for Medical Degrees (*Part I.*)*: Organic Chemistry.*—This examination will take place twice in each year, commencing on the Thursday following the second Monday in March and on the Thursday following the first Monday in July. No candidate will be admitted to this examination until he has completed the First Examination.

The Second Examination for Medical Degrees (*Part II.*) takes place twice in every year, commencing on the Tuesday following the third Monday in March and on the Tuesday following the first Monday in July. No candidate shall be admitted to the examination unless he has passed the First Examination for Medical Degrees at least 18 months previously, and has passed Part I. of the Second Examination for Medical Degrees.

The Third or M.B., B.S. Examination.—The M.B., B.S. examination takes place twice in each year, commencing on the second Monday in November and on the first Monday in May. No candidate will be admitted to this examination unless he has completed the Second Examination for Medical Degrees, together with a course of study summarised below, nor within three years from the date of passing the Second Examination, Part II., in Anatomy and Physiology. The course of study comprises introductory course in (1) Clinical Medicine; (2) Clinical Surgery; and (3) Clinical Pathology; (4) Experience as Clinical Clerk; (5) Clinical Medicine; (6) (*a*) Fevers, (*b*) Children's Diseases, (*c*) Venereal Diseases, (*d*) Mental Diseases (at a recognised Asylum), (*e*) Dermatology, (*f*) Vaccination, (*g*) Materia Medica and Pharmacy; (7) Experience as a Surgical Dresser; (8) Clinical Surgery; (9) Ophthalmology; (10) Oto-Rhino-Laryngology; (11) (*a*) Operative Surgery, (*b*) Applied Anatomy, (*c*) Administration of Anæsthetics, (*d*) Dental Surgery, (*e*) Orthopædic Surgery; (*f*) Mechano-therapeutics; (12) Obstetrics and Gynæcology; (13) Lying-in Hospital; (14) The conduct of at least 20 Labours; (15) Antenatal Clinic; (16) Experience as a Clinical Clerk in Gynæcological Work; (17) General Pathology, Morbid Anatomy, Bacteriology, and Chemical Pathology; (18) Work in the Post-Mortem Room; (19) Clinical Laboratory; (20) Forensic Medicine; (21) Hygiene. He must have attended the Medical and Surgical Practice of a recognised hospital for two years, and have held the posts of clinical clerk and surgical dresser for periods of six months each. Candidates will be examined in Medicine, Pathology, Forensic Medicine and Hygiene, Surgery, Obstetrics and Gynæcology. The subjects may be divided into two groups—namely: (1) Medicine, Pathology, Forensic Medicine, and Hygiene; and (2) Surgery, Obstetrics, and Gynæcology. These groups may be taken either separately or together. Bachelors of Medicine who graduated before May, 1904, may obtain the B.S. by passing the Surgical part of the M.B., B.S.

Doctor of Medicine.—The examination for this degree takes place twice in each year, commencing on the second Monday in December and on the first Monday in July. Candidates may present themselves for examination in one of the following branches—namely: (1) Medicine; (2) Pathology; (3) Psychological Medicine; (4) Midwifery and Diseases of Women; (5) State Medicine; and (6) Tropical Medicine. Any candidate for the degree of M.D. (except in branch 5) may transmit to the Registrar a thesis for approval and may be exempted from a part or from the whole of the written examination.

Master of Surgery.—The examination for the degree of Master of Surgery takes place twice in each year: (1) Surgery; (2) Dental Surgery; (3) Ophthalmology; (4) Laryngology, Otology, and Rhinology. A thesis may be submitted as for M.D.

Bachelor of Pharmacy.—The course extends over three years.

Full details of the prescribed curricula can be obtained free on application to the Academic Registrar, University of London, South Kensington, S.W.7.

MEDICAL SCHOOLS OF THE UNIVERSITY OF LONDON.[1]

ST. BARTHOLOMEW'S HOSPITAL AND COLLEGE.—The hospital contains 757 beds, of which 687 are for patients in the hospital at Smithfield and 70 at the Alexandra Hospital, Swanley. Special departments have been organised for Diseases of Women and Children, the Eye, Ear, Larynx, and Skin, as well as for Orthopædic and Dental Surgery, and for Electro-therapeutics and X Ray work. Whole-time Clinical Units under Professors of Medicine and Surgery have been established.

Ten house physicians and ten house surgeons are appointed annually, are provided with rooms and board, and receive £80 a year as salary. A resident midwifery assistant, an ophthalmic house surgeon, and a house surgeon for diseases of the throat, nose, and ear, and a house surgeon for orthopædic surgery are appointed every six months, and are provided with rooms and board and receive a salary of £80 a year. Three resident administrators of anæsthetics are appointed, the senior for one year at a salary of £150, and two juniors for six months with a salary at the rate of £80 per annum with board and rooms. An extern midwifery assistant is appointed every three months, and receives a salary of £80 a year. The clinical clerks, the obstetric clerks, the clerks to the medical out-patients, the dressers to the surgical in-patients and to the out-patients, and the dressers in the special departments are chosen from the students. A residential College is attached to the hospital.

There are quarters for the resident staff, casualty, medical, surgical, and special out-patient departments, casualty wards, dispensary, and clinical lecture theatre. There is a chemical laboratory attached to the College as well as a laboratory devoted to instruction in Public Health. A block is devoted to Pathology, and contains the post-mortem room as well as extensive laboratories for bacteriology, clinical pathology, and pathological chemistry. *The Medical College Buildings* include three large lecture theatres, a large dissecting room, laboratories for chemistry, biology, morbid anatomy and histology, and public health, as well as a spacious library (containing 14,500 volumes), a well-appointed museum of anatomy, physiology, comparative anatomy, materia medica, botany, and pathological anatomy. The pathological museum is complete. A new block in Giltspur-street has recently been acquired and has been fitted up as lecture theatres and laboratories for physics, chemical physiology, experimental physiology, histology, and pharmacology.

Special Classes for the Primary and Final F.R.C.S. are held twice yearly. *Instruction in Preliminary Science* is given to University of London students in chemistry, biology, and physics throughout the year. Facilities for research work are afforded in the Clinical Units and Laboratories of pathological and other departments. *A Vacation Post-graduate Course*, adapted to general practitioners, is given annually.

Scholarships given in aid of Medical Study.—For five of the Scholarships and the Exhibition—namely, (*a*), (*b*), two Entrance Scholarships in Science of the respective values of £75 and £100; (*c*) Entrance

---

[1] Of these schools that of the Royal Free Hospital is reserved for women; University College admits men and women to the whole course, the number of women being limited; King's College admits men and women to the Intermediate subjects; the remainder admit men only.

Scholarship in Arts, £100; (*d*) Jeaffreson Exhibition, £50; and (*e*) Shuter Scholarship, £50—a full or University course at St. Bartholomew's Hospital is required. The awards of (*a*) and (*b*) are made after examination in selections from the subjects of Chemistry, Physics, Zoology, Botany, Physiology, Anatomy, and Pathology; (*c*) and (*d*) are awarded after examination in Mathematics, Latin or Greek or French or German, a second language or Chemistry or Physics; (*e*) is awarded after competitive examination among Cambridge Graduates in Anatomy and Physiology. The more important of the other Scholarships and prizes are as follows:—Four Junior Scholarships—(*f*) No. 1, £30, Anatomy and Physiology; (*g*) No. 2, £20, Anatomy and Physiology; (*h*) No. 3, £25, Chemistry, Physics, and Biology; (*i*) No. 4, £15, Chemistry, Physics, and Biology: (*j*) Senior Scholarship, £50, Anatomy, Physiology, and Chemistry; (*k*) Kirkes Scholarship, £30 and medal, Clinical Medicine; (*l*) and (*m*) two Brackenbury Scholarships, £39 each, one in Medicine and one in Surgery; (*n*) Sir G. Burrows Prize, 10 guineas, Pathology; (*o*) Skynner Prize, 13 guineas, Regional and Morbid Anatomy; (*p*) Matthews Duncan Medal and Prize, £20, Midwifery and Gynæcology; (*q*) Luther Holden Research Scholarship in Surgery, awarded by election, £105; (*r*) Lawrence Research Scholarship and Gold Medal in Pathology, awarded by election, £115; and (*s*) Baly Scholarship in Clinical Medicine, £75, awarded by examination.

The recreation ground of 10 acres is at Winchmore Hill for the use of the members of the Students' Union, which all students are expected to join. The Students' Union contains a large reading and smoking room, a committee and writing room, luncheon and dining hall, and a miniature rifle range.

Information may be obtained on application to the Dean of the Medical College: Dr. T. W. Shore. The Warden of the Residential College is Mr. R. M. Vick.

CHARING CROSS HOSPITAL.—The Hospital, to which the School is attached, contains 300 beds. There are special departments for Mental Diseases, Midwifery, Diseases of Women, of Children, of the Skin, Ear, Throat, Nose, and Teeth, for Orthopædic Cases, X Ray work, and for Electrical Treatment.

In the Medical School Demonstratorships and Assistant Demonstratorships are open to students of the School. Six House Physicians, six House Surgeons, two Obstetric and Gynæcological House Surgeons, and two House Surgeons to the Special Departments are appointed annually. The large proportion of resident appointments to the number of students makes it probable that a student of ordinary ability will be able to obtain one of these appointments.

The following appointments are open to students after they have held resident appointments: Resident Medical Officer, at a salary of £400 per annum: Registrar to the Medical, Surgical, Obstetrical and Ear, Nose, and Throat Departments, at £150 per annum.

By an agreement with the University of London the School sends its Primary and Intermediate Students to receive their lectures and practical work at King's College, which is situated within four minutes' walk.

Final studies are taken in the school and hospital, where systematic lectures, demonstrations, and tutorial classes are arranged to cover all the subjects necessary for qualifying examinations. Departments are also available for other final subjects of Materia Medica and Operative Surgery.

An Institute of Pathology with a whole-time staff of scientific workers and fully equipped laboratories has been established. Students receive their training in Preventive Medicine, Pathology, Bacteriology, and Biochemistry here, and are encouraged to undertake research. Special facilities are available for post-graduate research and study.

The course in Ophthalmology is given in the Royal Westminster Ophthalmic Hospital. Special demonstrations are arranged for Post-graduates.

One Epsom School Scholarship, two Oxford and Cambridge Scholarships, and one Scholarship in Anatomy and Physiology open to students of King's College, are offered for competition each year. In addition there are a number of Exhibitions.

The Museum contains over 4000 specimens, including a notable collection of over 800 gynæcological specimens, the Cuthbert Lockyer Collection.

The social comfort and convenience of students are met by library, reading, and smoking-rooms, refreshment-room, in a Students' Club. The Club, which is under the control of a committee of students, provides needful athletic recreation, and includes also a medical society.

Further information may be obtained on application to the Dean, Dr. F. H. Young.

ST. GEORGE'S HOSPITAL.—This hospital has a service of 436 beds, of which 180 are allotted to surgical, 150 to medical cases, and 100 are at the Convalescent Hospital at Wimbledon. There are all the usual special clinical departments. One ward is set apart for Diseases Peculiar to Women, and there is a Maternity Ward of 11 beds. Children's beds are placed in the women's wards. There are two ophthalmic wards.

Twelve house physicians, 12 house surgeons, and 12 casualty officers are appointed annually. Special attention is directed to the following paid appointments, among others, which are open to students after they have held house office:—Resident Assistant Physician and Resident Assistant Surgeon, at £350 per annum each; Medical Officer to the Atkinson-Morley Convalescent Hospital, at £300 per annum; Medical Registrarship at £200 per annum, Surgical Registrarship at £200; Assistant Curatorship of the Museum at £100; Obstetric Assistantship (Resident) at £50; the post of Resident Anæsthetist at £100; the posts (3) of Junior Anæsthetists, each at £30.

Entrance Scholarships and Endowed Prizes of a total value of £700 are awarded annually; a detailed list is placed below. The entire teaching and laboratories are now devoted to purely clinical subjects, and arrangements have been made with the authorities of King's College for students who enter the first, second, or third year of the curriculum as students of St. George's to carry out the necessary courses of instruction at that College. Students then complete their course, without payment of any entrance fee, in a school entirely devoted to clinical work.

Scholarships and Prizes.—At this school five entrance scholarships are given, the money value and the subjects of examination being as follows: (*a*) and (*b*) two William Brown Exhibitions, £120 and £80 respectively; (*c*) and (*d*) two University Entrance Scholarships, 90 guineas and £70 respectively; (*e*) Devitt-Pendlebury Scholarship, £50, Anatomy and Physiology, except in the case of (*c*), subject of examination for which is General Pathology.

This year, in addition to these Scholarships, Exhibitions, each of the value of £40 and up to six in number, will be awarded to candidates of approved merit in the Entrance Scholarships Examination. The others are as follows: (*f*) Allingham Scholarship in Surgery for Students qualified not more than two years, £85; (*g*) and (*h*) two Brackenbury Prizes, one in Medicine and one in Surgery, £33 each, open to students of not more than five years' standing; (*i*) H. C. Johnson Memorial Prize, £19, Practical Anatomy; (*j*) Pollock Prize, £23, Physiology, Physiological Chemistry, and Histology; (*k*) Clarke Prize, £5; (*l*) Thompson Medal, £9, Clinical Reports; (*m*) Brodie Prize, £8, Clinical Reports; (*n*) Webb Prize, open to perpetual pupils, £34, Bacteriology; (*o*) Sir Francis Laking Memorial Prize, £65, open to students having registrable qualifications.

The First Examination for Medical Degrees (*Inorganic Chemistry, Physics, including Mechanics, and General Biology*) will take place twice in each year, commencing on the Monday following Dec. 7th and on the first Monday in July. It must be passed not less than nine months after matriculation.

The Second Examination for Medical Degrees (*Part I.*) *: Organic Chemistry.*—This examination will take place twice in each year, commencing on the Thursday following the second Monday in March and on the Thursday following the first Monday in July. No candidate will be admitted to this examination until he has completed the First Examination.

The Second Examination for Medical Degrees (*Part II.*) takes place twice in every year, commencing on the Tuesday following the third Monday in March and on the Tuesday following the first Monday in July. No candidate shall be admitted to the examination unless he has passed the First Examination for Medical Degrees at least 18 months previously, and has passed Part I. of the Second Examination for Medical Degrees.

The Third or M.B., B.S. Examination.—The M.B., B.S. examination takes place twice in each year, commencing on the second Monday in November and on the first Monday in May. No candidate will be admitted to this examination unless he has completed the Second Examination for Medical Degrees, together with a course of study summarised below, nor within three years from the date of passing the Second Examination, Part II., in Anatomy and Physiology. The course of study comprises introductory course in (1) Clinical Medicine; (2) Clinical Surgery; and (3) Clinical Pathology; (4) Experience as Clinical Clerk; (5) Clinical Medicine; (6) (*a*) Fevers, (*b*) Children's Diseases, (*c*) Venereal Diseases, (*d*) Mental Diseases (at a recognised Asylum), (*e*) Dermatology, (*f*) Vaccination, (*g*) Materia Medica and Pharmacy; (7) Experience as a Surgical Dresser; (8) Clinical Surgery; (9) Ophthalmology; (10) Oto-Rhino-Laryngology; (11) (*a*) Operative Surgery, (*b*) Applied Anatomy, (*c*) Administration of Anæsthetics, (*d*) Dental Surgery, (*e*) Orthopædic Surgery; (*f*) Mechano-therapeutics; (12) Obstetrics and Gynæcology; (13) Lying-in Hospital; (14) The conduct of at least 20 Labours; (15) Antenatal Clinic; (16) Experience as a Clinical Clerk in Gynæcological Work; (17) General Pathology, Morbid Anatomy, Bacteriology, and Chemical Pathology; (18) Work in the Post-Mortem Room; (19) Clinical Laboratory; (20) Forensic Medicine; (21) Hygiene. He must have attended the Medical and Surgical Practice of a recognised hospital for two years, and have held the posts of clinical clerk and surgical dresser for periods of six months each. Candidates will be examined in Medicine, Pathology, Forensic Medicine and Hygiene, Surgery, Obstetrics and Gynæcology. The subjects may be divided into two groups—namely: (1) Medicine, Pathology, Forensic Medicine, and Hygiene; and (2) Surgery, Obstetrics, and Gynæcology. These groups may be taken either separately or together. Bachelors of Medicine who graduated before May, 1904, may obtain the B.S. by passing the Surgical part of the M.B., B.S.

Doctor of Medicine.—The examination for this degree takes place twice in each year, commencing on the second Monday in December and on the first Monday in July. Candidates may present themselves for examination in one of the following branches—namely: (1) Medicine; (2) Pathology; (3) Psychological Medicine; (4) Midwifery and Diseases of Women; (5) State Medicine; and (6) Tropical Medicine. Any candidate for the degree of M.D. (except in branch 5) may transmit to the Registrar a thesis for approval and may be exempted from a part or from the whole of the written examination.

Master of Surgery.—The examination for the degree of Master of Surgery takes place twice in each year: (1) Surgery; (2) Dental Surgery; (3) Ophthalmology; (4) Laryngology, Otology, and Rhinology. A thesis may be submitted as for M.D.

Bachelor of Pharmacy.—The course extends over three years.

Full details of the prescribed curricula can be obtained free on application to the Academic Registrar, University of London, South Kensington, S.W. 7.

MEDICAL SCHOOLS OF THE UNIVERSITY OF LONDON.[1]

ST. BARTHOLOMEW'S HOSPITAL AND COLLEGE.—The hospital contains 757 beds, of which 687 are for patients in the hospital at Smithfield and 70 at the Alexandra Hospital, Swanley. Special departments have been organised for Diseases of Women and Children, the Eye, Ear, Larynx, and Skin, as well as for Orthopædic and Dental Surgery, and for Electro-therapeutics and X Ray work. Whole-time Clinical Units under Professors of Medicine and Surgery have been established.

Ten house physicians and ten house surgeons are appointed annually, are provided with rooms and board, and receive £80 a year as salary. A resident midwifery assistant, an ophthalmic house surgeon, and a house surgeon for diseases of the throat, nose, and ear, and a house surgeon for orthopædic surgery are appointed every six months, and are provided with rooms and board and receive a salary of £80 a year. Three resident administrators of anæsthetics are appointed, the senior for one year at a salary of £150, and two juniors for six months with a salary at the rate of £80 per annum with board and rooms. An extern midwifery assistant is appointed every three months, and receives a salary of £80 a year. The clinical clerks, the obstetric clerks, the clerks to the medical out-patients, the dressers to the surgical in-patients and to the out-patients, and the dressers in the special departments are chosen from the students. A residential College is attached to the hospital.

There are quarters for the resident staff, casualty, medical, surgical, and special out-patient departments, casualty wards, dispensary, and clinical lecture theatre. There is a chemical laboratory attached to the College as well as a laboratory devoted to instruction in Public Health. A block is devoted to Pathology, and contains the post-mortem room as well as extensive laboratories for bacteriology, clinical pathology, and pathological chemistry. *The Medical College Buildings* include three large lecture theatres, a large dissecting room, laboratories for chemistry, biology, morbid anatomy and histology, and public health, as well as a spacious library (containing 14,500 volumes), a well-appointed museum of anatomy, physiology, comparative anatomy, materia medica, *The patho-* botany, and pathological anatomy. logical museum is complete. A new block in Giltspur-street has recently been acquired and has been fitted up as lecture theatres and laboratories for physics, chemical physiology, experimental physiology, histology, and pharmacology.

Special Classes for the Primary and Final F.R.C.S. *Instruction in Preliminary* are held twice yearly. *Science* is given to University of London students in the year. chemistry, biology, and physics throughout the Clinical Facilities for research work are afforded in the other Units and Laboratories of pathological and departments. *A Vacation Post-graduate Course*, adapted to general practitioners, is given annually.

Scholarships given in aid of Medical Study.—For five of the Scholarships and the Exhibition—namely, (*a*), (*b*), two Entrance Scholarships in Science of the respective values of £75 and £100; (*c*) Entrance the firm in elementary medicine and surgery, and who assists the honorary members of the firm in the preparation of their demonstrations. In the department of Obstetrics and Gynæcology there are two assistants and two resident accoucheurs. Special courses of lectures and demonstrations are arranged in Medicine and Surgery and their ancillary subjects. Opportunities for research are provided under the supervision of the staff.

---

[1] Of these schools that of the Royal Free Hospital is reserved for women; University College admits men and women to the whole course, the number of women being limited; King's College admits men and women to the Intermediate subjects; the remainder admit men only.

Owing to the large number of patients more appointments are open to students before and after qualification than at any other hospital. Holders of resident appointments have free board. Special classes are held for the examinations of the University of London, for the Fellowship of the Royal College of Surgeons, for the Membership of the Royal College of Physicians, and for other higher examinations. Special entries for medical and surgical practice can be made.

A Clinical Unit in Medicine, under the charge of a whole-time director, provides for the more elaborate methods of diagnosis and treatment, and takes a leading part in the initiation and coördination of medical research. The director has an assistant director, two assistants, and two house physicians.

Scholarships and Prizes.—The following is a list of the Scholarships and Prizes :—Price Scholarship £100, and one Entrance Scholarship of £50, subjects of First Medical Examination at the University of London; Epsom College Scholarship, free education, subjects of First Medical Examination as above; Price Scholarship, open to students of Oxford and Cambridge Universities, (1) £100, Pathology; (2) £75, Human Anatomy and Physiology; Buxton Prize, £40, subjects of Anatomy and Physiology; three Prizes for Clinical Work, £20 each, Medicine, Surgery, and Obstetrics and Gynæcology; Sutton Prize, £20, Pathology; Duckworth Nelson Prize, biennial, £10, Practical Medicine, and Surgery; Letheby Prizes (2), £25, Chemistry and Chemical Pathology; four Dressers' Prizes, amounting to £20, zeal, efficiency, and knowledge of Elementary Clinical Surgery; Hutchinson Prize, triennial, £60, Clinical Surgery; Treves Prize, £15, Clinical Surgery; two Practical Anatomy Prizes, £6 and £4 respectively; Andrew Clark Prize, £14, Clinical Medicine and Pathology; T. A. M. Ross (Prox. Acc.) Prize, £10 10s., Clinical Medicine and Pathology; James Anderson Prizes (4), £20, Elementary Clinical Medicine; Arnold Thompson Prize, £15, Diseases of Children; K. E. D. Payne Prize, Research Scholarship, £20, Pathology; and Liddle Prize, triennial, £120.

Medical Research Funds.—Funds to the value of over £90,000 permit of financial assistance being given to students and graduates engaged in Medical Research.

Two Residential Hostels are provided for students. The recent additions to the hospital and college buildings include the Dunn Clinical Laboratories. The Bearsted Clinical Theatre, the Bernhard Baron Institute of Pathology, and a hostel for 40 resident medical officers. The Union Athletic Ground, 13 acres, is within easy reach of the hospital.

Dean: Prof. William Wright.

ST. MARY'S HOSPITAL.—The Hospital and Medical School have on one side a poor district of 500,000 persons, and on the other side the residential districts of Kensington and Bayswater. The hospital contains 350 beds and structural additions during the past year have added two new operating theatres. By a scheme of affiliation, for teaching purposes, of certain neighbouring hospitals, the teaching facilities extend over 1000 beds. The Medical School provides complete courses of instruction, and students can join at once on passing a Preliminary Examination in Arts. Terms begin in October, January, and April.

Clinical Units in Medicine and Surgery were established in 1920. Lying-in beds have recently been added, and, in addition to this, arrangements have been made by which all students take out a short course of instruction in Practical Midwifery at Queen Charlotte's Hospital without additional fee.

Students specially interested in Pathology and Bacteriology have singular advantages at St. Mary's. The institute comprises seven special departments, the whole being under the personal direction of Sir Almroth Wright. Certain Research Scholarships of £200 each are awarded annually to students working in the departments of the institute; and research beds have been instituted. Clerkships in Pathology, Bacteriology, and Chemical Pathology, lasting for a period of three months, are open to students of the fifth year, and enable them to carry out the Pathological and Bacteriological investigations of the wards, and learn the necessary technique under supervision. Seventy-two of these posts are available annually. Numerous appointments are open to newly qualified members of the Medical School, including ten salaried posts with salaries varying from £200 to £750 per annum.

Entrance Scholarships.—Two Entrance Scholarships of the value of £210 each are awarded annually, by nomination in July, the Geraldine Harmsworth Scholarship, £200, and one or more University Scholarships of £200 are awarded in July.

The Athletic ground (10 acres) is situated at Wembley and can be reached in 20 minutes by a constant service of trains. A large pavilion has recently been added.

For further information apply to the Dean of the Medical School.

MIDDLESEX HOSPITAL.—The hospital contains over 450 beds, with special wards for Cancer, Maternity and Gynæcological and Ophthalmological cases, and for Diseases of Children. Other special departments include those for Diseases of the Eye, Ear, Nose and Throat, and Skin; Nervous diseases, Orthopædic cases, Diseases of the Rectum and Venereal Diseases. There is also an Electrotherapeutic department. The Cancer Charity, containing 92 beds and Special Investigation Laboratories, offers unrivalled opportunities for the study of Cancer, both in its clinical and pathological aspects. In the Electrotherapeutic Department, students obtain instruction in the Treatment of Lupus and Cancer by the X ray method of treatment.

All appointments are made without fee of any kind, and the following are appointed at intervals annually: six house physicians, eight house surgeons, two obstetric and gynæcological house surgeons, two casualty medical officers, two casualty surgical officers, four resident anæsthetists, and four resident officers to the special departments. The medical and surgical casualty officers are appointed twice a year. Nine registrars are appointed annually. Non-resident qualified clinical assistants are appointed to assist in the various out-patient departments. Clinical clerks and surgical dressers are also appointed in every department.

The Medical School, which includes the Bland-Sutton Institute of Pathology, the Courtauld Institute of Biochemistry, and the Cancer Research Laboratories is fully equipped for the theoretical and practical teaching of all the subjects of the medical curriculum, and for the Diplomas in Public Health, for which two courses are held yearly. Ample laboratory and class-room accommodation is provided. The teaching staff includes 6 Professors, 32 recognised Teachers, 10 Demonstrators, 4 tutors. The Bland-Sutton Institute of Pathology is completely equipped for routine hospital investigations, teaching and research work, and contains a lecture theatre, large pathological, bacteriological, and clinical laboratories, also smaller laboratories for individual research work. A well-equipped Anatomical and Pathological Museum and Reference Library offer every facility.

Other features of interest are: the course in Medical Radiology and Electrology, under the direction of the "Joel" Professor of Physics; D.P.H. course, under the direction of Dr. Charles Porter, M.O.H., St. Marylebone, Prof. J. McIntosh, and Prof. W. B.

The St. George's Hospital Club, with smoking- and luncheon-rooms is on the hospital premises and an athletic ground at Wimbledon, is an amalgamation of the Hunterian Society, the *Gazette*, and the Rugby football, cricket, lawn tennis, boxing, rifle, and golf clubs. Students have the advantage of a library of medical and scientific books which is kept up to date.

Further information may be obtained from the Dean of the Medical School, Dr. A. Feiling.

GUY'S HOSPITAL.—This hospital contains 642 beds. The whole of the medical school has been rebuilt within recent years. It provides ample accommodation, with modern equipment, for all the non-clinical subjects of the medical curriculum.

The following special departments are attached to the hospital: Departments of ophthalmology, laryngology, gynæcology, diseases of children, diseases of the nervous system, dermatology, otology, actino-therapeutics, anæsthetics, dentistry, orthopædics, vaccine, tuberculosis, genito-urinary and venereal diseases, Salomon's Welfare Centre (for Maternity and Children). Dresserships and clerkships in the various special departments are held by students in turn.

There is a Venereal Clinic, in accordance with the Scheme of the Local Government Board and London County Council. Lectures and clinical instruction are given, to which Medical Students and Practitioners are admitted without fee.

House physicians, house surgeons, out-patient officers, assistant house surgeons, obstetric residents, house surgeons in the departments of ophthalmology, laryngology, and genito-urinary diseases, house physicians in the department for diseases of children, and clinical assistants are appointed from among recently qualified students according to merit.

Scholarships.—Six entrance scholarships are awarded annually as follows:—(*a*) one War Memorial scholarship, of the value of £200, to be awarded alternately in Arts and Science (next award, June or July, 1930 in Science); (*b*) one Open Arts Scholarship of £100 for students under 19 years of age; candidates may offer themselves in either of the following groups: (1) English and any two of the following—viz., Latin, Greek, or Mathematics; (2) English and any two of the following—viz., French, German, and Mathematics; (*c*) one Open Junior Science scholarship for students under 20 years, £100; subjects, any three of the following: Inorganic Chemistry, Physics, Biology, and Mathematics; (*d*) a confined Junior Science scholarship of the value of £100 is offered for competition, annually in June or July, to candidates who have attended the Preliminary Science Classes at this School; (*e*) two open Senior Science scholarships: (1) a War Memorial scholarship of the value of £100, awarded annually in September; (2) an open scholarship of the value of £80, awarded annually in September, for students who have completed the curriculum for, or passed the examinations in, Anatomy and Physiology for a medical degree in any University of the British Empire, and who, during the nine months immediately preceding the Scholarship examination, have not entered as students in any Metropolitan Medical School other than Guy's; subjects, any two of the following:—Anatomy, Physiology, Organic Chemistry and Pharmacology, General Pathology.

Within the grounds of the hospital are situated the residential college, with accommodation for 35 students, the students' club, with reading, smoking, luncheon, and dining-rooms, a fives court, and swimming bath. The athletic ground and club house is situated at Honor Oak Park, and can be reached in 15 minutes from the hospital.

Further information can be obtained from the Dean of the Medical School, Prof. T. B. Johnston.

KING'S COLLEGE HOSPITAL.—The final subjects in the curriculum are taught at the Medical School of King's College Hospital, which is situated at Denmark Hill, S.E. 5.

The hospital has 400 beds, and provision will ultimately be made for 600. There are special departments for Bacteriology, Children, Clinical Pathology, Dermatology, Gynæcology and Obstetrics, Laryngology, Massage, Neurology, Odontology, Ophthalmology, Orthopædics, Otology, Physical Treatment, Psychological Medicine, Radiology, Rhinology, and Urology, each in charge of a specialist and his staff. Clinics are also held in applied pharmacology, cardiology, and medical chemistry.

Appointments.—The appointments open to students are those of clinical assistant to the special departments; medical, surgical, obstetric, and pathological tutorships; resident casualty officers, house physicians and house surgeons; resident anæsthetist; resident radiologist; bacteriologist; clinical pathologist; pathological, medical, surgical, and obstetrical registrarships. Sixteen resident medical and surgical officers are appointed half-yearly.

Scholarships and Registrarships (those in connexion with King's College have already been enumerated).—Scholarships of the total value of £1095 are awarded annually. These include (*a*) Medical Entrance Scholarships—Science, £50; Anatomy and Physiology, £50; Pathology, £75; (*b*) two Burney Yeo Entrance Scholarships, £80 each, open to students of Oxford and Cambridge on the recommendation of the Regius Professors; (*c*) two Raymond Gooch Scholarships, £120 each, open to students of British Universities on certain conditions; (*d*) an Epsom College Scholarship, value £50 at least, offered annually to a student of Epsom College who has taken the first part of the courses for Medical Degrees at the Universities of Oxford, Cambridge, or London; (*e*) a Seaman Scholarship, £50 a year for a period not exceeding five years, restricted to the sons of poor clergymen of the Church of England; (*f*) Senior Scholarship (Clinical Studies), £40. The holders of the Warneford and Sambrooke Scholarships awarded by King's College are required to take the subjects of the preliminary and intermediate examinations at King's College, and the final subjects at King's College Hospital. Three Sambrooke Registrarships, open to matriculated stidents who have filled certain appointments in hospital.

Prizes.—Tanner Prize, £10, Obstetrics and Diseases of Women; Todd Prize, £4 4*s.* and medal, Clinical Medicine; Burridge Prize, £4 4*s.*, Forensic Medicine; Jocelyn Almond Prize, £5 5*s.*, Diseases of Children; Wallis Prize, £10, History of Dentistry; 13 Class Prizes, £3 each.

The King's College Hospital Clubs and Societies Union consists of the Listerian and Musical Societies, the Students' Common Rooms, and the various athletic and sports clubs. The athletic ground, over six acres in extent, is on Dog Kennel Hill, about ten minutes' walk from the hospital. There are also Tennis Courts in the grounds of the Hospital and of "The Platanes"—a hall of residence for students belonging to the hospital.

The Calendar of the School will be sent on application to either of the following: Dr. H. Willoughby Lyle, Dean; Mr. S. C. Ranner, Secretary of the Medical School.

LONDON HOSPITAL.—The hospital, with its Medical College and Dental School, is situated in Mile End-road, and contains 837 beds. There are special departments for diseases of the Eye, Ear, Nose and Throat, Skin, Teeth, and Pediatric, Orthopædic, Venereal, Radiological, Electro- and Physico-therapeutical and Inoculation Departments.

To each medical and surgical firm throughout the hospital there is attached a First Assistant, who is responsible for instructing the clerks or dressers of

30 residents and students), the extension to the Nurses' Home, and new research laboratories for the Medical School are now finished and in full occupation. Twelve women students are admitted annually.

Those who are desirous of carrying out original research in Pathology, including Morbid Anatomy, Bacteriology, Experimental Pathology, and Chemical Pathology, are admitted to work in the laboratories of the school by the Professor of Pathology, and under certain conditions can receive grants from the Charles Graham Medical Research Fund. A special course of instruction is given in conjunction with University College for preparation for the examinations for Diplomas in Public Health of the various universities and examining bodies. In the Dental School in Great Portland-street, formerly known as the National Dental Hospital, there is afforded the opportunity for attending lectures and practical instruction in diseases of the mouth and teeth.

Appointments.—Clerkships and dresserships to the physicians, surgeons, anæsthetist, and pathologist are allotted amongst the students of the hospital. Maternity students are appointed each month and reside in the Students' House connected with the Medical School and Hospital. Fourteen house physicians, six house surgeons, ten obstetric assistants, two house surgeons to the Royal Ear Hospital (of the total number of resident officers not more than three may be held by women students at any one time) are selected annually by examination from among the senior students who have a medical qualification. All house officers reside free in the hospital. In addition to these posts there are certain special appointments which are vacant from time to time and are filled by senior students of the hospital: Resident Medical Officer, Surgical Registrar, Medical Registrar, Obstetric Registrar, Harker-Smith Cancer Registrar, Ophthalmic Registrar, Registrar to the Royal Ear Hospital, Casualty Medical Officer and a Casualty Surgical Officer, Assistants in Ear and Throat, Skin and Venereal Diseases Departments, and House Anæsthetist.

Scholarships and Prizes (those in connexion with University College have already been enumerated).—At this School the first two Scholarships (*a*) and (*b*) entitle the holder to a complete course at University College and University College Hospital Medical School; the second two (*c*) and (*d*) entitle to a final course at the Medical School. The money value and subjects of examination are as follows:—(*a*) Entrance Scholarship, Bucknill, 135 guineas, Chemistry, Physics, Botany, and Zoology; (*b*) Epsom Free Medical Scholarship, subjects of Preliminary Scientific Examination and Nomination by Epsom College; (*c*) and (*d*) two Goldsmid Entrance Exhibitions 112 guineas each, Anatomy or Physiology, or General Pathology; (*e*) Graham Scholarship in Pathology, £300 per annum for two years, awarded by the Senate of the University of London; (*f*) Atkinson Morley Scholarship, tenable for three years, £45 per annum, Surgery; (*g*) Atchison Scholarship, tenable for two years, £55 per annum, General Proficiency in Medical Studies; (*h*) Magrath Clinical Scholarship, about £150, Clinical Cases; (*i*) Percival Alleyn Scholarship, about £75, Surgery; (*j*) Filliter Exhibition, £30, Pathology; (*k*) Erichsen Prize, £10 10s., Practical Surgery; (*l*) two Senior and two Junior Fellowes Clinical Medals for Clinical Medicine; (*m*) two Liston Gold Medals for Clinical Surgery; (*n*) Alexander Bruce Gold Medal for Pathology and Surgery; and (*o*) Tuke Silver and Bronze Medals for Pathology, (*p*) Radcliffe Crocker Travelling Scholarship for Dermatology. (*q*) Leslie Pearce Gould Travelling Scholarship for Surgery.

The *Museum of Pathological Anatomy* is open for study daily, and microscopic sections of most of the specimens have been prepared and are available for the use of students on application to the Curator. The Anatomical Museum of the University of London, University College, is open to all students of University College Hospital and Medical School on the recommendation of the School Committee. The Medical Library, open daily to every student of the School, contains about 20,000 works on medical subjects, including all the current text-books and works of reference required for study or research.

The Medical Society of University College Hospital Medical School exists for the dual purpose (1) of promoting the study of medical and surgical science, and (2) of promoting social intercourse among its members. All male students of the Medical School are required to become members. Meetings are held once a fortnight for the purpose of discussing subjects connected with the study of medicine. In its social aspect the society includes various athletic clubs and superintends the gymnasium and squash racquet court in the Medical School, and the Athletic Ground at Perivale.

University College Hall, Ealing, is recognised by the authorities as a residential hostel. The Students' House in University-street contains large and comfortable rooms. The Maternity Students occupy them on payment of a moderate charge.

Full information can be obtained from the Dean of the School.

WESTMINSTER HOSPITAL.—The Hospital contains 240 beds. By a scheme for the concentration of the teaching of the preliminary and intermediate subjects of the curriculum, which has the support of the London University, an arrangement has been made by the Westminster School for the teaching of these subjects at King's College. Students, however, may join the Westminster Medical School as formerly and may compete for Entrance Scholarships as heretofore. There are separate departments for Diseases of the Eye, Skin, Teeth, Ear, Nose, and Throat, for Orthopædic practice, for Diseases of Women, for Diseases of Children, for Radiography, for Venereal Diseases, and for Massage, Electrical and Light Treatment. The Anatomical, Pathological, and Materia Medica Museums are open to all students of the school.

The usual registrarships and house appointments are open to students.

Scholarships and Prizes.—The following Entrance Scholarships are offered for competition: Winter Session: Two Scholarships in Anatomy and Physiology, £75 each. Summer Session: Two Scholarships in Anatomy and Physiology, £75 each. A certain number of Scholarships have been allotted to Universities of England, Wales, and the Colonies, and to Public Schools. These Scholarships are awarded entirely on the nomination of the principal of the university or school. During the period of study the following prizes may be competed for: Sturges Prize in Clinical Medicine, about £6, Reports on Cases; Clinical Surgery Prize, £5, Reports on Cases; Chadwick Prize, £21 in books or instruments—Medicine and Surgery, including Pathology and Applied Anatomy and Physiology; Frederic Bird Medal and Prize, open to Fourth-year Students, £14 in medal and books or instruments—Midwifery, Diseases of Women, Medicine, Pathology, Forensic Medicine and Bacteriology, and Public Health and Toxicology; Abrahams Prize in Clinical Pathology, 5 guineas, a Paper and Tests in Practical Work; Alfred Hughes Memorial Prize, open to Second-year Students, about £5 in books or instruments—Anatomy; Huxley Memorial Prize, 3 guineas in books or cash, open to Second-year Students—Physiology; Carter Gold Medal and Prize for Botany, open to Students of not more than three years' attendance, gold medal and books of the joint value of £15; Jelf Medal awarded to Third-year Students; Second-year Scholarship £20, Elementary Anatomy, Physiology, Histology, and Organic Chemistry; Daniell Scholarship, £40, Chemistry; Rabbeth Scholarships open to First-year Students, one of £30 and one of £15; Class Examinations in the Preliminary Scientific Course.

The Athletic Grounds are situated in Tooting and are reached in 20 minutes from the hospital.

Inquiries should be addressed to the Dean of the Medical School.

Tuck. A primary F.R.C.S. course is held twice yearly, and special classes to prepare students for the Intermediate Examinations of the Universities.

Scholarships and Prizes.—Two Entrance Scholarships, value £100 each, and two University Scholarships, value £90 and £60, are awarded annually in September. The successful candidates are required to become general students of the school. A Freer Lucas Scholarship is awarded annually on the nomination of the Headmaster of Epsom College. There are also two Broderip Scholarships, value £60 and £40 respectively; the Lyell Gold Medal and Scholarship, value £55 5*s.*; the John Murray Medal and Scholarship, value £25 (awarded every third year); the Freeman Scholarship, value £30; the Hetley Clinical Prize, value £25; the Leopold Hudson Prize, value 11 guineas; and the Second Year's Exhibition, value 10 guineas. There are also numerous class prizes.

The Amalgamated Students' Club includes the following: Medical Society, Common Room Society, Musical Society, cricket club, football clubs, athletic club, rowing club, chess club, lawn tennis club, and hockey club. There are a restaurant and gymnasium in the school buildings, and large athletic grounds at N. Wembley, with new pavilion.

For further particulars apply to the Dean or the Secretary of the Medical School.

ST. THOMAS'S HOSPITAL.—This Hospital contains 644 beds. There are special departments for the treatment of women, children, diseases of the eye, ear, nose and throat, skin, teeth, and for orthopædics. Nervous and mental diseases are treated in special departments. An electrocardiograph has been installed for the investigation of diseases of the heart. The Tuberculosis Department forms a part of the Lambeth scheme for treatment of patients and for instruction. The Venereal Department has been established as part of the London County Council scheme. Departments for Radiology, Electrotherapy, Phototherapy, Massage and Remedial Physical Exercises are also special features. A speech clinic has been inaugurated in connexion with the Children's Department. Exceptional facilities are offered in the hospital laboratories for the study of General Pathology, Clinical Pathology, Chemical Pathology, and of Treatment by Serums and Vaccines. Surgical operations take place in the main theatres every day, except Saturdays, at 2 P.M. Clinical teaching in the wards, out-patients' and special departments, is available every day of the week. Clinical lectures are delivered every Wednesday during the sessions. A Clinical Unit in Medicine has been established.

All appointments in the hospital are open to students without extra fee. Clinical clerks and dressers for in- and out-patients are selected from students who have completed their third years' work. Every student acts as clerk in the post-mortem room and in one of the pathological laboratories, takes his turn on maternity duty under proper supervision in the maternity ward and district, thus obviating any necessity for seeking instruction elsewhere. Students are instructed in the administration of anæsthetics by the hospital anæsthetists.

The arrangements are made to meet the requirements of all the Examining Bodies. Special classes are held for the examinations at the University of London and for the First and Final Fellowship Examinations of the Royal College of Surgeons of England. Tutorial classes in all subjects precede the various examinations. The hospital is easily accessible from all parts.

Appointments.—A Resident Assistant Physician and a Resident Assistant Surgeon, salary £225 each per annum, and a Resident Anæsthetist, salary £200 per annum, are appointed annually. Two Hospital Registrars, Medical and Surgical, at an annual salary of £250 each are appointed yearly. The tenure of these offices may be renewed for a term not exceeding two years. A Pathological Registrar to the Department of Obstetrics and Gynæcology (at an annual salary of £250), an Ophthalmic Registrar (at an annual salary of £50), and an Orthopædic Registrar (unpaid) are appointed yearly. Two Senior Resident Casualty Officers (Medical and Surgical) are appointed yearly. Eight Resident Casualty Officers and Anæsthetists are appointed every six months. Seven House Physicians (including two Obstetric House Physicians, and one House Physician to the Department of Diseases of Children), nine House Surgeons (including two Ophthalmic House Surgeons, one Orthopædic House Surgeon, and two House Surgeons to the Ear, Nose and Throat Department) are appointed every six months. Clinical Assistants in the Special Departments are appointed every three months, and hold office for six months if recommended for re-election. There are three Assistants in the Department of Pathology; the Senior receives £600 a year, and the two Juniors £450 each.

Scholarships and Prizes.—At this school there are five Entrance Scholarships—namely, two in Arts, equivalent to the tuition fees for the first year of study; two in Natural Science, of the value of £150 and £60 respectively; and the University Scholarship of £100 in any two of the following: Anatomy, Physiology, Pathology, Chemistry. The value of all entrance scholarships must be taken out in tuition fees. The money value and subjects of examination of the remainder are as follows: (*a*) William Tite Scholarship for second-year students, £25; (*b*) and (*c*) Musgrove Scholarship or (alternately) Peacock Scholarship, each for third-year students and tenable for two years, £3[illegible] each; (*d*) Mead Medal, Medicine, Pathology and Hygiene; (*e*) Wainwright Prize, Medicine; (*f*) Toller Prize, Medicine; (*g*) Cheselden Medal, Surgery and Anatomy; (*h*) Clutton Memorial Medal in Clinical Surgery, biennial; (*i*) Beaney Scholarship, £5[illegible], biennially, Surgery and Surgical Pathology; (*j*) Solly Medal and Prize, biennial, Reports of Cases; (*k*) Sutton Sams Prize, biennial, Report of Cases; (*l*) Bristowe Medal, Pathology and Morbid Anatomy; (*m*) Hadden Prize, Pathology and Morbid Anatomy; (*n*) Grainger Testimonial Prize, £31 10*s.*, Anatomy and Physiology; (*o*) Louis Jenner Research Scholarship, tenable for two years, £60 annually, Pathology; *(p) School Council Research Scholarship,* £250 per annum, tenable for two years; (*q*) John and Temple Research Fellowship, tenable for two years, £450, Children.

St. Thomas's House, the New Students' Club recently opened, comprises spacious dining-, smoking-, and reading-rooms, and accommodation for some 60 resident students. There is no occasion for students to leave the hospital premises during working hours.

Further information may be obtained from the Medical Secretary of the School, St. Thomas's Hospital.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.—The final subjects in the curriculum are taught at the Medical School of the hospital, which has 526 beds, including 74 in the new obstetric hospital. The course of instruction is suitable for the examinations at the *Universities of Oxford*, Cambridge, Durham, and other British Universities, and for the medical education required by the Examining Board in England and the Society of Apothecaries. Clinical Units in Medicine, Surgery, and Obstetrics and Gynæcology are now in operation. The whole-time Directors of the Units are concerned with the organisation of the teaching generally, but the honorary staff are responsible for the largest share of the teaching in the wards and Out-patient Department of the hospital. The department of otology, rhinology, and laryngology (*the Royal Ear* Hospital) has been provided with a separate building in Hunter-street, adjacent to the obstetric hospital. It contains 39 beds, including eight private wards for *patients of limited means.* The hospital is equipped with all modern appliances for investigation. The new buildings of the Obstetric Hospital of 74 beds (rendered possible by the *Rockefeller Benefaction*), the new Residents' House (with accommodation for date must submit to the Professor of Surgery the course of study he proposes to follow, and this course must be approved by the Board of the Faculty of Medicine. One year shall be devoted mainly to work in the departments of Anatomy, Physiology, Pathology, and Bacteriology, and the candidate must submit evidence of having so worked. Not less than six months of another year must be spent as resident surgeon in a recognised teaching hospital, and the rest of the year in the study of surgery in a recognised medical centre. Not less than six months of one of the three years must be spent in surgical study abroad.

Candidates for any of the above degrees, diplomas, or licence must give at least 28 days' notice to the Secretary of Examinations, University of Durham College of Medicine, Newcastle-upon-Tyne. In the case of the M.D. (essay) examination candidates must send in their essays before April 1st.

Scholarships and Prizes.—The following are awarded:—University of Durham Entrance Scholarship, £25 a year for four years; Pears' Entrance Scholarship, £40 a year for three years (awarded every third year; Heath Entrance Scholarship (from Kepier Grammar School), £60 (renewable); Province of Durham Masonic (Entrance) Scholarship, £60 (renewable); Heath Scholarship for Surgery, £200, available every second year; Rutherford Morison Surgical Scholarship, £180, available every third year.

The following Scholarships are tenable for one year, namely:—Tulloch Scholarship for Elementary Biology and Organic Chemistry, £20; Dickinson Scholarship for Medicine, Surgery, Midwifery, and Pathology; Gold Medal and £20; Charlton Scholarship for Medicine, £25; Gibb Scholarship for Pathology, £28; Luke Armstrong Scholarship for Comparative Pathology, £25; Stephen Scott Scholarship for Surgery, £40; Philipson Scholarships for highest marks in Final M.B., B.S. Examinations, two of £48 each; Goyder Memorial Scholarship for Clinical Medicine and Clinical Surgery, interest on £325; Gibson Prize for Midwifery and Diseases of Women and Children, £10; Turnbull Prize and Silver Medal for Surface Anatomy; and Outterson Wood Prize for Psychological Medicine, £10; Sewell Memorial Prize and Silver Medal for Clinical Pathology.

For further information apply to the Dean of the College.

COLLEGE OF MEDICINE, Newcastle-upon-Tyne.—Hospital practice is carried out at the Royal Victoria Infirmary, a general hospital containing more than 550 beds, and there are facilities for the study of the various special subjects.

Practical midwifery can be studied at the Princess Mary Maternity Hospital, which contains 90 beds, with an annual indoor and outdoor attendance on 3000 cases.

The bacteriological laboratory is adjacent to Armstrong College.

A *Students' Union* has been erected and furnished at a cost of over £54,000, and is now in daily use. Special accommodation has been provided for women students.

NEWCASTLE-UPON-TYNE ROYAL VICTORIA INFIRMARY.—The Infirmary has 572 beds. Clinical Lectures are delivered by the Physicians and Surgeons weekly and ward demonstrations are given daily. Tutorial classes are held by specially appointed Medical Tutors, Assistant Surgeons and Senior Assistant in the Gynæcological Department, and demonstrations are given in the several out-patient departments daily. Pathological demonstrations are given by the Pathologist daily or as opportunity occurs, and in the new buildings nothing has been spared in perfecting scientific equipment. In addition to medical and surgical in-patient and out-patient departments the following special departments are fully equipped for teaching students: Ophthalmic, Throat, Nose, and Ear, Skin, Gynæcological, and Electrical. The hospital building contains the following laboratories: 1. Special Pathological Laboratory, attached to the post-mortem rooms. 2. Bacteriological Laboratory in which all clinical bacteriological investigations are carried out with a view to treatment by vaccines and serums. 3. There is in addition a Clinical Laboratory attached to each ward and to the out-patient department. There are five operating theatres in use in the hospital. The winter session of 1928 opens on Oct. 2nd and the summer session of 1929 on April 11th.

Applications for detailed information should be made to the Sub-Dean, Dr. Horsley Drummond, at the hospital.

Practical Midwifery is studied at the Princess Mary Maternity Hospital, a new building, excellently equipped, with 90 beds. Instruction is given in Psychological Medicine at the City of Newcastle Mental Hospital. A special course of instruction is given in the City Hospital for Infectious Diseases by the City Officer of Health. Ophthalmology is taught at the Northumberland, Durham, and Newcastle Infirmary for Diseases of the Eye.

Post-graduate Instruction.—1. General courses in Clinical Medicine, Surgery, and Pathology at the Royal Victoria Infirmary, meeting once weekly for ten weeks. One course will be held from October to December and one from April to June. 2. Special courses of clinical instruction, meeting once weekly for ten weeks, in the following subjects: Gynæcology; Diseases of the Eye; Diseases of the Throat, Nose, and Ear; Diseases of the Skin; Venereal Diseases; Neurology; Diseases of Children: Electrotherapeutics and Radiology; special courses in Midwifery will be held at the Princess Mary Maternity Hospital. 3. An intensive course of 14 days' duration in the early part of the Summer Vacation. 4. In addition to the regular post-graduate courses practitioners may attend the ordinary medical and surgical practice of the Royal Victoria Infirmary, and also at the Princess Mary Maternity Hospital, for specified periods.

UNIVERSITY OF BIRMINGHAM.

The University of Birmingham grants the degrees of M.B., Ch.B., M.D., Ch.M., and Ph.D. (for Research Study), and also a degree and a diploma in Public Health. The course for the Bachelors' degrees extends over five years from the date of commencement of professional study. As a rule the first four of these years must be spent in the University, but the Senate has power of recognising attendance at another University as part of the attendance qualifying for these degrees and of recognising examinations passed at such other Universities as exempting from the examinations in Biology and Organic Chemistry. In the case of such students at least three years must be spent in attendance upon classes at the University. The fifth year may be spent at any other medical school recognised by the University.

Degrees of Bachelor of Medicine and Bachelor of Surgery.—The student must have passed the Matriculation Examination of the Joint Board or an examination accepted in lieu thereof, and a recognised Pre-Medical Examination in Chemistry and Physics. All communications respecting the Matriculation Examination, and examinations accepted in lieu thereof, must be sent to the Secretary, Joint Matriculation Board, 315, Oxford-road, Manchester. First Examination.—Part I., Elementary Biology and Organic Chemistry; Part II., Anatomy and Physiology. Second Examination.—General Pathology and Bacteriology, Materia Medica, and Pharmacy. Third Examinations (at the end of the fourth year).—Forensic Medicine, Toxicology, Public Health, and Therapeutics. Two years' hospital work must have been accomplished. Final Examination.—Medicine, Surgery, Midwifery, Diseases of Women, Mental Diseases, and Ophthalmology. Attendance at a general hospital for a year after the passing of the third examination will be required, also attendance at a fever hospital three months, maternity hospital three months, and mental hospital three months.

ROYAL FREE HOSPITAL, LONDON: SCHOOL OF MEDICINE FOR WOMEN.—The Royal Free Hospital contains 268 beds. The Hospital also has large Casualty and Out-patient Departments, and Departments for Special Diseases. A new and specially equipped block contains the Obstetrical and Gynæcological Unit, which controls 68 beds. A Children's Department, including 18 cots, an Orthopædic Department, and a Light Department have recently been added to the Hospital. Maternity Districts are attached to the Unit operating in the Gray's Inn-road and Essex-road areas. Students also attend the in-patient and out-patient practice of the Elizabeth Garrett Anderson Hospital, Cancer Hospital, Hospital for Sick Children, Great Ormond-street, National Hospital for Paralysed and Epileptic, South London Hospital, and Royal London Ophthalmic Hospital.

A Clinical Unit in Obstetrics has been established. Courses are arranged for the Primary Fellowship Examination of the College of Surgeons; also for dental students in conjunction with the Royal London Dental Hospital, Leicester-square.

The School buildings have been entirely rebuilt in recent years, and there are spacious, well-equipped laboratories, which afford every facility for efficiency of teaching and practical work in all departments.

There are residential chambers at 8, Hunter-street, 25, Gordon-square, 9 and 16, Brunswick-square, 5, Mecklenburgh-square, and 36, Tavistock-square, and the Warden can be consulted on the subject of other residences for students.

Students after qualification can hold the posts of house physicians, house surgeons, obstetric assistants. clinical assistants, assistant anæsthetist, medical, gynæcological, and surgical registrars, and assistant pathologist; and at the Medical School the posts of demonstrators in the departments of Anatomy, Physiology, Pharmacology, Biology, Chemistry, and Physics. Many other resident posts in London and elsewhere are also open to them.

Scholarships and Prizes.—(*a*) Isabel Thorne Scholarship, £30. (*b*) St. Dunstan's Medical Exhibition, £60 a year, tenable for three or five years. (*c*) Mrs. George M. Smith Scholarship, £50 a year, tenable for three or five years. (*d*) Bostock Scholarship, tenable for two or four years, £90 (*e*) Mabel Sharman-Crawford Scholarship, tenable for four years, £20 a year. (*f*) Sir Owen Roberts Scholarship, £75 a year for four years. (*g*) Mabel Webb Research Scholarship, tenable for one year and renewable, £30, Physiology, Chemistry, or Pathology. (*h*) Fanny Butler Scholarship, tenable for four years; next award in July, 1931, £16. (*i*) John Byron Bursary, tenable for two years, for students already in the School requiring assistance for the prosecution of their medical studies; application to the Secretary by March 31st next, £20. (*k*) Helen Prideaux Prize and Julia Ann H. Cock Prize, awarded alternately every year to a student who has become qualified during the two years immediately preceding the award, and to be spent in assisting the holder to further study, £60 each. (*l*) Dr. Edith Pechey Phipson Post-graduate Scholarship of the value of £100, awarded annually in June. It is open to all medical women, preferably coming from India, or going to work in India, for assistance in Post-graduate study. (*m*) Sarah Holborn Scholarship, value £20 a year for three or five years, awarded every alternate year; next award in 1929. (*n*) Dr. Margaret Todd Scholarship, tenable for four years, £37 10s. a year, awarded in alternate years; next award in July, 1929. (*o*) Lieutenant Edmund Lewis and Lieutenant Alan Lewis Memorial Scholarship, tenable for four years, awarded every four years; next award in July, 1928. (*p*) Alfred Langton Scholarships, tenable two years, one awarded annually, £50 a year. (*q*) School Jubilee Bursary, tenable for three years, £50 a year. (*r*) Flora Murray Bursary, awarded every year to a fifth-year student, £50. The Dorothy Chick Gift, £20, is awarded annually for efficiency in Practical Midwifery. Two Richardson-Kuhlmann Prizes are given each year, value £12, for proficiency in Clinical Obstetrics, value £8, for proficiency in senior subjects respectively. Two Evans Prizes of £2 2s. and £1 1s. are given each year on the results of the class examination in Midwifery. The Evans Prize for Operative Midwifery, value £5 5*s.*; the Dr. Helen Webb Prize for Children's Diseases, £5 5*s.*; the Mary Swann Prize in Gynæcology, £5 5*s.*; *the* Edward Hanson Prize in Physiology, £2 10*s.*; *and the* Edith Pechey Phipson Prize in Pharmacology, value £3 3*s.*, are awarded annually.

The Students' Union *arranges the* social, athletic, and other clubs and societies. The School sports ground, consisting of 7½ *acres of* freehold land, is situated at Sudbury (easily reached from Euston Station).

Inquiries may be addressed to the Warden and Secretary of the Medical School, 8, Hunter-street, London, W.C.

UNIVERSITY OF DURHAM.

The University of Durham grants degrees of Bachelor of Medicine, Bachelor of Surgery, Doctor of Medicine, Master of Surgery, Doctor of Surgery, Bachelor of Hygiene, Doctor of Hygiene, Bachelor of Dental Surgery and Master of Dental Surgery, the Diploma in Public Health, Diploma in Psychiatry, and a Licence in Dental Surgery.

For the degrees of *Bachelor of Medicine* and *Bachelor of Surgery* there are four professional examinations. The subjects of the First Examination are—Elementary Biology and Organic Chemistry. The subjects of the Second Examination are—Anatomy and Physiology. The subjects of the Third Examination are—Materia Medica, Pharmacology, general principles of Therapeutics and Pharmacy, Medical Jurisprudence, Public Health, and Pathology and Bacteriology. The subjects of the Fourth Examination are—Medicine, Clinical Medicine, Surgery, Clinical Surgery, Operative Surgery, Midwifery and Gynæcology, Psychological Medicine, Diseases of the Skin, of the Throat, Nose, and Ear, and of Children, and Ophthalmology. It is required that at least one of the five years of professional education shall be spent at the University of Durham College of Medicine, Newcastle-upon-Tyne.

For the degrees of *Doctor of Medicine* and *Master of Surgery* a candidate must not be less than 24 years of age. He must also have obtained the degrees of Bachelor of Medicine and Surgery of the University of Durham, and must have been engaged for at least two years subsequently to the date of admission to these degrees in research work, or in attendance on the practice of a recognised hospital, or in the naval or military services, or in medical or surgical practice. The candidate for the M.D. degree may present an essay or undergo a special examination in the subjects of Medical Anatomy, Medical Pathology, and the Principles and Practice of Medicine. The subjects of examination for the M.S. are:—Principles and Practice of Surgery, Surgical Pathology, Surgical Anatomy, Surgical Operations, Clinical Surgery.

Doctor of Medicine (without residence).—The University of Durham has instituted a special examination whereby the degree of Doctor of Medicine may be obtained without residence. Candidates must not be under 40 years of age and must have been in active practice for 15 years as registered medical practitioners. They must also produce certificates of moral character from three registered members of the medical profession. The fee is 50 guineas (including the degree fee), of which 20 guineas is retained if the candidate fails to satisfy the examiners.

Doctor of Surgery.—The University of Durham grants the Degree of Doctor of Surgery. Candidates for this degree must be registered medical practitioners, and not less than 24 years of age. They must devote three years, subsequently to obtaining a registrable qualification, to the study of Surgery and ancillary subjects. One at least of the three years must be spent in the University. The candi-

Degrees of Bachelor of Medicine and Bachelor of Surgery.—Candidates for the degrees of Bachelor of Medicine and of Surgery must have attained the age of 22 years on the day of graduation. At least two of the five years of medical study must have been passed in the University, and one year at least must have been passed in the University subsequently to the date of passing the First Examination. The other three years may be passed at any college or medical school recognised for this purpose by the University. Candidates must pass three examinations entitled respectively: the First Examination, the Second Examination, and the Final Examination. The subjects of the First Examination are: (1) Chemistry; (2) Physics; (3) Biology (Zoology and Botany). The subjects of the Second Examination are (*a*) (1) Anatomy; (2) Physiology (including Physiological Chemistry and Histology); and (*b*) (3) Elementary Bacteriology, (4) Clinical Chemistry, (5) General Pathology. Candidates may present themselves in (*a*) or (*b*) separately. The subjects for the Final Examination are: (*a*) (1) Special Pathology and Morbid Anatomy; (2) Forensic Medicine and Toxicology; (3) Public Health; (4) Pharmacology and General Therapeutics; (*b*) (5) Obstetrics and Diseases of Women; (6) Surgery, Systematic, Clinical, Operative and Practical, including Ophthalmology; (7) Medicine, Systematic and Clinical, including Therapeutics, Mental Diseases, and Diseases of Children. Candidates may present themselves in Parts (*a*) and (*b*) separately, but candidates must have completed the fifth year of medical study before taking Part (*b*).

Degrees of Doctor of Medicine and Master of Surgery. No candidate will be admitted to the degree of Doctor of Medicine or Master of Surgery unless he has previously received the Degrees of Bachelor of Medicine and Bachelor of Surgery, and at least two years have elapsed since he passed the examinations for those degrees. Candidates for the degree of Doctor of Medicine are required to present a thesis together with, if desired, published original work relative to medical science. and unless the thesis is of special merit to submit to an examination in medicine, or to a special written or oral examination on subjects connected with the thesis.

The University also awards a *Diploma in Medical Radiology and Electrology*—Part I., Physics: Part II., Radiology and Electrology. The parts may be taken at one examination or separately.

Scholarships, Fellowships, and Prizes.—The following are awarded: (*a*) Robert Gee Entrance Scholarship (Men), annually, of £42 10*s*.. tenable for four years; (*b*) Lyon Jones Scholarship, No. 1, of £21 per annum, tenable for two years, Competitive Examination among Junior Students in First M.B. Subjects; (*c*) Lyon Jones Scholarship, No. 2, of £21, Competitive Examination on results of Professional Examination in Anatomy, Physiology, Elementary Bacteriology, Clinical Chemistry, and General Pathology; (*d*) Derby Exhibition of £15, Competitive Examination among Fourth- or Fifth-year Students in Clinical Subjects, and (*e*) Clinical School Exhibition of £15 annually for Fourth- or Fifth-year students; (*f*) University Scholarship of £50 for one year, awarded on results of the Final (Part A) Examination for the degrees; (*g*) Holt Fellowships, Physiology and Pathology, of £150 each, for one year; (*h*) Gee Fellowship, Anatomy, of £100, for one year; (*i*) John Rankin Fellowships in Anatomy, two, each of the value of £120, tenable for two years; (*j*) Johnston Colonial Fellowship, Biochemistry, of £100, for one year; (*k*) John W. Garrett International Fellowship, Bacteriology, of £100, for one year; (*l*) Thelwall Thomas Fellowship, Surgical Pathology, of £150, for one year; (*m*) Ethel Boyce Fellowship in Gynæcological Pathology, of £100 for one year; (*n*) Mary Birrell Davies Memorial Fund Scholarship, of the value of £80, tenable for four years, offered for competition in alternate years; open only to women students who will have attained the age of 19 on the first day of October next following the award; (*o*) Rankin Exhibition in Practical Anatomy, of £25, for one year; (*p*) Lady Jones Research Fellowship in Orthopædic Surgery, £200; (*q*) Samuels Memorial Scholarships, three at £20; numerous prizes and medals.

The Medical School.—All the laboratories and classrooms are situated close together, communicating with one another, and are made up of four large blocks of buildings which form one side of the College quadrangle. There are the Johnston Laboratories for Experimental Medicine and Biochemistry; the Medical School for Anatomy, Surgery, Toxicology, and Ophthalmology; and the Thompson-Yates Laboratories for Physiology and Pathology. There is also a separate building for Tropical Medicine. Medical research has also been endowed with several new laboratories in which students can pursue research work after graduation.

Clinical Studies.—The Clinical School of the University consists of four general hospitals—the ROYAL INFIRMARY, the DAVID LEWIS NORTHERN HOSPITAL, the ROYAL SOUTHERN HOSPITAL, and the STANLEY HOSPITAL; and of six special hospitals—the Eye and Ear Infirmary, the Hospital for Women (with the Samaritan Hospital), Liverpool Maternity Hospital, the Royal Liverpool Children's Hospital, St. Paul's Eye Hospital, and St. George's Hospital for Skin Diseases. These hospitals contain in all a total of about 1445 beds. The organisation of these hospitals to form one teaching institution provides the medical student and the medical practitioner with a field for clinical education and study which is unrivalled in extent in the United Kingdom. All the hospitals are within easy access of the University. There are a large number of appointments to house physicianships and surgeonships both at the general and special hospitals which are open to qualified students of the school.

Public Health Department.—This is located in a separate building, in which full courses of instruction are given to students for the Diplomas and Degrees of the University and of other Examining Boards.

Prospectuses and further information may be had on application to the Dean of the Faculty of Medicine, University of Liverpool.

VICTORIA UNIVERSITY OF MANCHESTER.

Four degrees in Medicine and Surgery are conferred by the University—viz., Bachelor of Medicine and Bachelor of Surgery (M.B. and Ch.B.), Doctor of Medicine (M.D.), and Master of Surgery (Ch.M.). A Diploma in Psychological Medicine, a Diploma in Public Health, and a Diploma in Bacteriology are awarded by examination to registered medical practitioners.

Degrees of Bachelor of Medicine and Bachelor of Surgery.—Before admission to the degree of M.B. or Ch.B. candidates are required to present certificates that they will have attained the age of 21 years on the day of graduation, and that they have pursued the courses of study required by the University Regulations during a period of not less than five and a half years subsequently to the date of their registration by the General Medical Council, two of such years having been passed in the University subsequently to the date of passing the first M.B. Examination.

The First Examination: (1) Chemistry and Physics; (2) (*a*) Botany, (*b*) Zoology. Candidates must have attended during at least six months' courses both of lectures and of laboratory work in each of the abovenamed subjects. The Examination is divided into two parts: Part I. Inorganic and Elementary Organic Chemistry and Physics; Part 2. (*a*) Botany, (*b*) Zoology. The candidates sit for these parts separately. The Second Examination: (1) Anatomy and Histology: (2) Physiology, including Physiological Chemistry. The Third Examination: (1) Pharmacology and Materia Medica; (2) Pathology. The Final Examination: (1) Medicine, Systematic and Clinical (including Mental Diseases and Diseases of Children); (2) Surgery, Systematic, Clinical, and Practical; (3) Obstetrics and Gynæcology (including Clinical and Practical); (4) Forensic Medicine (including an Oral Examination); (5) Hygiene and Preventive Medicine. The Final Examination is divided into two parts: Part I., Forensic Medicine, Hygiene and Preventive Medicine; Part II., Medicine, Surgery, Obstetrics and Gynæcology (Systematic, Clinical, and Oral). Candidates for the Second Part must have completed the sixth year of medical study.

Degree of Doctor of Medicine.—Candidates are not eligible for the degree of Doctor of Medicine unless they have previously obtained the degrees of Bachelor of Medicine and Bachelor of Surgery and at least one year has elapsed since they passed the examination for those degrees. Candidates may elect either (1) to present an original dissertation; or (2) to undergo an examination. The dissertation must embody the results of personal observation or original research, either in some department of medicine or of some science directly relative to medicine. The examination, which will be written and practical, is in the Principles and Practice of Medicine, in Pathology, and in some other subject to be selected by the candidate.

Degree of Master of Surgery.—Candidates are not eligible for the degree of Master of Surgery unless they have previously obtained the degrees of Bachelor of Medicine and Bachelor of Surgery and at least one year has elapsed since they passed the examination for those degrees. The degree is conferred in the following branches: Surgery (Branch I.), Gynæcology (Branch II.), Ophthalmology (Branch III.), Laryngology, Otology, and Rhinology (Branch IV.).

Degrees of B.Sc. and M.Sc.—The ordinary degree of B.Sc. in the Schools of Anatomy and Physiology may be obtained by students in Medicine who in their third year of study for the degree of M.B., Ch.B. complete the additional courses in these subjects prescribed for this degree. Candidates for the Honours degree of B.Sc. in Anatomy or Physiology, who are students in Medicine, are required to attend courses in advanced Anatomy and Physiology for four terms after passing the Second Examination for the degrees of M.B., Ch.B. Graduates in science may proceed to the degree of M.Sc. by presentation of an approved thesis.

Scholarships, Fellowships, and Prizes.—The following are offered in connexion with medical study at the Victoria University:—Scholarships: Dreschfeld Entrance (triennial), £20; John Russell Medical Entrance, £45; Sam Gamble Entrance for Women; Graduate Entrance (fees up to 160 guineas); two Dauntesey Medical Junior, £50 each; Dauntesey Medical Senior, £50; Professor Tom Jones Exhibition in Anatomy, £25; Dickenson Trust Scholarships in Anatomy and Pathology; Platt Physiological, £90; Graduate Research Scholarship, £70; Dickenson Trust Travelling Scholarships in Medicine and Surgery; Ashby Memorial in Diseases of Children (triennial), £100; John Henry Agnew in Diseases of Children, £120. Fellowships: Leech Research, £70; Professor Tom Jones, Surgical, £105; Morrison Watson in Anatomy, £150; Delépine in Preventive Medicine (biennial), £300; Honorary Research Fellowships. Prizes: Sidney Renshaw in Physiology, £15; Turner Medical, £20; Dumville Surgical, £15; Knight Prize in Psychological Medicine, £50; Graduate Prizes, £5 each. There are many general entrance scholarships, in addition to those already mentioned, open for competition, the examinations for which are held in the month of May. Full particulars can be obtained from the Registrar.

The Medical School.—This school, largely extended in 1920, is provided with dissecting-rooms, X ray rooms, physiological laboratories, private laboratories, and work-rooms, besides lecture-rooms, museums, and general and departmental libraries. A special laboratory is equipped for experimental work on the central nervous system. In the pathological laboratories ample provision is made for the teaching of pathology and bacteriology and for the prosecution of original research. The Helen Swindells Laboratory is specially equipped for cancer research and investigation in general pathology. Ample facilities for investigation are provided in Anatomy, Physiology, and Materia Medica. In the public health department, which is lodged in a separate institute in York Place, near the Royal Infirmary, suitable laboratory accommodation is provided for the study of sanitary chemistry, physics, and practical bacteriology in the departments of chemistry and physics and in that of pathology.

Clinical Studies.—The clinical and practical departments of medical study are taught partly in the Medical School and partly in the Royal Infirmary and St. Mary's Hospitals for Women and Children, a fever hospital, mental hospitals, a convalescent home, and other special hospitals. Medical and Surgical Clinical Classes are conducted in the Infirmary, and separate instruction is afforded in the elements of Medical and Surgical Physical Diagnosis, in Obstetric Medicine, Ophthalmic Surgery, and Pathological Anatomy by the different members of the staff of the Medical School and Infirmary.

Post-graduate Studies.—Post-graduate Courses in Medicine and Surgery have been arranged for during 1928–29 as follows, in addition to those usually held at the various hospitals: 1. Whole-time intensive courses in (*a*) Medicine and Surgery, and (*b*) Obstetrics and Gynæcology. 2. Part-time courses in (*a*) Diseases of the Eye, (*b*) Application of Radiology to Medicine in Diagnosis and Treatment, (*c*) Diseases of the Skin, (*d*) Clinical Pathology. 3. Clinical Assistantships. Syllabuses and other information may be had on application to the Dean of the Medical School, Manchester University.

MANCHESTER ROYAL INFIRMARY.—The Manchester Royal Infirmary is built on the pavilion system, near the University, and has accommodation for 668 patients (including 54 beds at the Central Branch). The medical side consists of four units, each unit having a testing-room for the scientific investigation of morbid products and a class-room. The surgical beds are also arranged in five units, each unit having its own operation theatre, with anæsthetising, recovery, sterilising, testing and apparatus rooms, and its own class-room attached. All of these units are occupied. In the educational block is a large lecture theatre and a museum. In the same building is housed the X ray department, which has nine separate X ray outfits for different purposes, and in which one large room is put aside specially for X ray demonstrations and teaching purposes. A large massage school is also connected with this department.

Associated with the Infirmary are: (1) the Convalescent Hospital at Cheadle, containing 132 beds; (2) the Royal Lunatic Hospital at Cheadle, accommodating with its branches 430 patients; and (3) the Central Branch in the City, which has now accommodation for 54 patients. The Associated Hospitals thus contain 1230 beds and are under the same management. Women students are admitted on the same terms as men.

Two Entrance Scholarships in Medicine of the value of £160 each are offered annually by the Council of the Manchester University and the Medical Board of the Manchester Royal Infirmary for proficiency in Arts and Science subjects respectively. Other scholarships and prizes are mentioned in the College syllabus. Numerous annual appointments and junior appointments may be held by those who have attended the practice of the Infirmary.

ROYAL MANCHESTER CHILDREN'S HOSPITAL, Pendlebury, Gartside-street, Manchester, and Lytham St. Anne's.—The hospital contains 190 beds and 30 in the Convalescent Home, Lytham St. Anne's. The medical staff visit the hospital daily at 10 A.M. Clinical instruction is given by the medical staff at the Hospital and Dispensary. There is a new Massage and Electrotherapeutic Department, also an Artificial Sunlight Department. Four Clinical Assistants are appointed for periods of six months. In throwing open these appointments to qualified medical men and women, the Board is actuated by the desire to aid those qualified medical men and women who wish to have opportunities for the further study of disease in children, or who wish to fit themselves for posts as Medical Officers to Children's Hospitals, to Child Welfare Centres, or for School Medical Officer appointments. There is an Orthopædic Department. Out-patients' day is on Tuesday at Gartside-street, and a ward at Pendlebury is devoted to cases needing operative treatment. Out-patients are seen daily at 9 A.M. at the Out-patient Department, Gartside-street, Manchester. Secretary: Mr. W. M. Humphry.

MANCHESTER NORTHERN HOSPITAL FOR WOMEN AND CHILDREN, Park-place, Cheetham Hill-road, Manchester.—The hospital contains 73 beds. Out-patients are seen daily from 8.30 to 12 noon.

UNIVERSITY OF LEEDS.

Four degrees in Medicine and Surgery are conferred—viz.: Bachelor of Medicine and Bachelor of Surgery (M.B. and Ch.B.), Doctor of Medicine (M.D.), Master of Surgery (Ch.M.), also Degrees and Diplomas in Dental Surgery and Diplomas in Public Health and in Psychological Medicine. The courses and Degrees in the Faculty are open to men and women alike.

Degrees of Bachelor of Medicine and Bachelor of Surgery.—Candidates for these degrees are required to present certificates showing that they will have attained the age of 21 years on the day of graduation, and have attended courses approved by the University extending over not less than five years, two of such years at least having been passed in the University, one of which must be subsequent to the date of passing the First Examination. Candidates must also satisfy the examiners in the several subjects of the following examinations, entitled respectively: the Matriculation Examination, or such other examination as may have been recognised by the Joint Matriculation Board in its stead; the First Examination; the Second Examination; and the Final Examination. The First Examination consists of: Part I., Physics and Inorganic Chemistry; Part II., Zoology and Botany. Candidates will be allowed to pass the two parts separately. The Second Examination consists of: Part I., Organic Chemistry; Part II., Materia Medica and Practical Pharmacy; Part III., Anatomy, Physiology; Part IV., Pharmacology. Candidates will be allowed to pass any parts separately, but Part I. must be passed before Parts II., III., or IV. The Final Examination consists of: Part I., Pathology and Bacteriology; Part II., Medicine, Surgery, Obstetrics, Gynæcology, and Clinical Pathology; Part III., Forensic Medicine, Public Health, and Therapeutics. Part I. may be taken at the end of the second clinical year, and Parts II. and III. may be taken at the end of the third clinical year, but not before the completion of the fifth year of medical study. If taken separately Part II. may be passed before Part III.

Degree of Doctor of Medicine and Master of Surgery.—Candidates are not eligible for the degree of Doctor of Medicine or Master of Surgery unless they have previously received the degrees of Bachelor of Medicine and Bachelor of Surgery of the University (or of Victoria prior to December, 1904) and at least two years' Hospital Practice or four years' other professional practice for the former, and one year has elapsed for the latter since they passed the examination for those degrees. Candidates for the degree of Doctor of Medicine may present a dissertation and, if the dissertation is considered to be of exceptional merit, will not be required to pass an examination. The first term commences on Oct. 1st. Prospectus can be obtained from the Academic Sub-Dean.

Post-graduate work.—Practitioners wishing to attend Infirmary practice during short periods, or post-graduate classes held by members of the clinical staff, may do so on application to the Clinical Sub-Dean, from whom particulars may be obtained.

Clinical Studies.—The clinical studies are pursued mainly at the Leeds General Infirmary, which has accommodation for 630 in-patients, including 88 beds at branch hospitals in the country. Clinical teaching takes place daily in the wards, and Clinical lectures are given in Medicine and Surgery by the Physicians and Surgeons. There are Medical, Surgical, Ophthalmic, Aural, Electrotherapeutic, and Radiographic Departments, in each of which special instruction is imparted to students. Gynæcological and Children's Departments, together with Laryngeal, Venereal, and Skin Clinics, are in operation, and there is a special ward for cases of nutritional disorders of children. Several valuable prizes are given at the end of each session. Numerous appointments at the Infirmary are annually open to students after qualification. Further particulars concerning these, and the scholarships and prizes open to competition, may be obtained from the Dean of the Faculty of Medicine.

In addition to work in the General Infirmary, clinical instruction in obstetrics is given in the Leeds Maternity Hospital and in mental and infectious diseases in the Wakefield (W.R.) Mental Hospital and Leeds City Fever Hospital respectively.

UNIVERSITY OF SHEFFIELD.

The Degrees in the Faculty of Medicine are Bachelor of Medicine and Bachelor of Surgery (M.B., Ch.B.), Doctor of Medicine (M.D.), and Master of Surgery (Ch.M.), Bachelor of Dental Surgery (B.D.S.), and Master of Dental Surgery (M.D.S.). There is also a Diploma of Licentiate in Dental Surgery. The courses and degrees in the Faculty of Medicine are open to men and women alike. Candidates must matriculate in the University or pass such other examination as may be recognised for this purpose by the University and sanctioned by the Joint Matriculation Board, and must pass also the further examination in Chemistry and Physics.

Degrees of Bachelor of Medicine and Bachelor of Surgery.—A candidate must have attained the age of 22 years on the day of graduation and have pursued the courses of study required by the University regulations during a period of not less than five years subsequently to the date of his matriculation and the passing of the further examination in Chemistry and Physics, three of such years at least having been passed in the University, one at least being subsequent to the passing of the First Examination. The subjects of the First Examination are Chemistry, Physics, and Biology. The Intermediate B.Sc. Examination in these subjects will, on payment of the required additional fee, be accepted instead of this examination. Candidates must, after matriculation and the passing of the further examination in Physics and Chemistry, and registration as medical students, have attended courses of instruction (lectures and laboratory work) in chemistry, physics, and biology for one year each. The Second Examination: The subjects are Anatomy and Physiology. Candidates must have completed the second year of professional study. The Third Examination: The subjects are Pathology, Pharmacology, Anatomy, and Physiology. Candidates must have completed the Lent Term of the fourth year of professional study. The Final Examination: The subjects of the examination are: Part I., Forensic Medicine and Public Health; Part II., Medicine (including Mental Diseases and Diseases of Children), Surgery, Obstetrics (including Gynæcology). Candidates for Part I. must have completed the Michaelmas Term of the fifth year of professional study; candidates for Part II. must have completed the fifth year of professional study.

Degree of Doctor of Medicine.—Candidates for the degree of Doctor of Medicine must have passed the examination for the degrees of M.B., Ch.B. at least one year previously, must present a thesis embodying observations in some subject approved by the professor of medicine, and must pass an examination in the Principles and Practice of Medicine.

Degree of Master of Surgery.—Candidates must have taken the M.B., Ch.B. at least one year previously, and must since have held for not less than six months a surgical appointment in a public hospital.

The subjects of examination are Systematic, Clinical, and Operative Surgery, Surgical Anatomy, Surgical Pathology and Bacteriology.

Scholarships and Prizes.—The following are awarded: Four Town Trustees scholarships, offered annually, each of the value of £50 per annum for three years. Medical: offered annually, covers cost of medical curriculum. Six Edgar Allen, offered annually, each of the value of £125 per annum for three years. Post-graduate: Frederick Clifford scholarship, value £50 per annum, tenable for two years. Mechanics' Institute scholarship, value £50 for one year, renewable for a second year. Town Trustees fellowship, value £75 for one year. Medals and Prizes: Kaye scholarship; Gold Medal in Clinical Medicine and Surgery; John Hall Gold Medal in Pathology; Holroyd Gold Medal in Anæsthetics; bronze medals. Particulars of all the above may be obtained from the Registrar.

The Medical School.—The Medical Department occupies the entire north wing of the University quadrangle. The various athletic and other students' societies are under the management of the Union Representative Council, elected annually. There are large and comfortable common rooms both for men and women students, and two Students' Unions, one for men and one for women. A refectory is open daily at the University where students may obtain meals and refreshments at moderate prices. The University journal, *Floreamus*, edited by a committee of staff and students, is published each term. The University Halls, "Oakholme," Clarkehouse-road; "Tapton Cliffe," Fulwood-road, and "Endcliffe University Hall," Endcliffe Vale-road, are recognised by the Senate as halls of residence for women students; full particulars may be obtained from the tutor for women students. Stephenson Hall is a hall of residence for men students; particulars may be obtained from the Warden.

Clinical Studies.—The University is within easy reach of the various hospitals with which it is connected for clinical purposes.

The SHEFFIELD ROYAL INFIRMARY (500 beds) provides all the opportunities of a large general hospital with special departments for Skin and Ear. The Sheffield Royal Hospital, 320 beds, has special out-patient departments for Diseases of the Throat, Ear, Skin, Orthopædics, and Mental Diseases. The two institutions are amalgamated for the purposes of clinical practice, medical, surgical, and special. There are special departments for the treatment of Diseases of the Eye, with wards assigned to them, at both hospitals, and excellent junior appointments. The Jessop Hospital for Diseases of Women, with 142 beds, has also a Maternity department, with about 900 in-patients per annum and about 250 out-patient cases attended. The Children's Hospital has 85 beds. Special courses on Fevers are held at the City Fever Hospitals (690 beds) and on Mental Diseases at the South Yorkshire Mental Hospital (1860 beds). Every facility is afforded in the various laboratories for the prosecution of advanced studies and research.

Post-graduate Courses.—Post-graduate courses of clinical instruction are held annually in the various hospitals connected with the School.

UNIVERSITY OF BRISTOL.

In the Faculty of Medicine there are the following degrees:—Bachelor of Medicine and Bachelor of Surgery (M.B. and Ch.B.), Doctor of Medicine (M.D.), Master of Surgery (Ch.M.), Bachelor of Dental Surgery (B.D.S.), and Master of Dental Surgery (M.D.S). There are also the following diplomas: Diploma in Public Health (D.P.H.), Diploma in Dental Surgery (L.D.S.), and Diploma in Veterinary State Medicine.

All candidates for degrees in Medicine, Surgery, and Dentistry are required to pass, at Matriculation standard, an examination called the School Certificate Examination, or to pass such examination as may be regarded as equivalent by the Senate. All courses, degrees, and diplomas are open to men and women alike.

Degrees of Bachelor of Medicine and Bachelor of Surgery.—Candidates shall be not less than 21 years of age and shall have pursued the courses prescribed by University Regulations during not less than five years after passing the first examination in Chemistry and Physics, of which three shall have been passed in the University, and two of these three subsequent to passing the second examination. All candidates for the degrees of M.B., Ch.B., are required to satisfy the examiners in the several subjects of three examinations. The First Examination: The subjects of examination are: Chemistry (Inorganic), Physics, and Biology, the courses pursued being those for the time being approved for the intermediate part of the B.Sc. curriculum. This part of the curriculum shall extend over one year. (Candidates who have passed the Higher School Certificate approved by the Board of Education in these subjects will not be required to sit for the first examination and will be regarded as having completed one year of study.) The Second Examination: The subjects of examination are: Organic Chemistry and Elementary Anatomy (Part I.) and Advanced Anatomy and Physiology (Part II.). The Final Examination: The subjects of examination are: Materia Medica and Pharmacy, Pharmacology and Therapeutics, General Pathology, Morbid Anatomy, and Bacteriology (Part I.); Special Pathology, Forensic Medicine, Toxicology, and Public Health, Obstetrics (including Diseases of Women), Surgery (Systematic, Clinical, Practical, and Operative), Medicine (Systematic, Clinical, and Practical, including Mental Diseases) (Part II.). The subjects included in Part II. may be taken in two groups—viz., Group I., Surgery and Obstetrics; Group II., Medicine, Public Health, Special Pathology, Forensic Medicine, and Toxicology. Candidates may pass Parts I. and II. together, or separately, and the two groups of Part II. may be taken together or separately. Forensic Medicine and Toxicology may be taken with Part I., or with Group II. of Part II.

Degree of Doctor of Medicine.—Candidates shall be Bachelors of the University of not less than two years' standing as such and may elect either (1) to pass an examination in General Medicine, or (2) to pass an examination in State Medicine, or (3) to present a Dissertation. The candidate who elects to pass the examination in State Medicine must hold a diploma in Public Health of some University or College, and the candidate who elects to present a Dissertation may be examined in the subject thereof.

Degree of Master of Surgery.—Candidates shall be Bachelors of not less than two years as such, during which period they shall have attended the Surgical Practice of an institution approved for the purpose. They shall pass an examination in Surgical Anatomy, Pathology, and Bacteriology, and Operative, Clinical, and General Surgery, and present to the University a Dissertation on some subject of Surgery. The degree may be taken also in General Surgery, and a Special Subject—e.g., Oto-Rhino-Laryngology, Ophthalmology, and Gynæcology.

Clinical Studies.—The allied hospitals (BRISTOL ROYAL INFIRMARY and BRISTOL GENERAL HOSPITAL) have between them about 600 beds and extensive out-patient departments, special clinics for Diseases of Women and Children and those of the Eye, Throat and Ear, in addition to large and well-equipped departments for Dental work and large outdoor Maternity Departments.

At each of these institutions there are well-arranged pathological museums, post-mortem rooms, and laboratories for Morbid Anatomy. There are also laboratories for work in Clinical Pathology, Bacteriology, and Cytology, in which special instruction is given in these subjects. Departments are provided and well equipped for X ray work, both for diagnosis and treatment, the various forms of Electrical treatment, including High-frequency Currents, Electric Baths, Finsen Light treatment, and Massage.

The students of the school also attend the practice of the Royal Hospital for Sick Children and Women, containing 140 beds, and that of the Bristol Eye Hospital, with 40 beds. The total number of beds available for clinical instruction is therefore about 750.

There are numerous salaried junior appointments for residents who are graduates.

Scholarships and Prizes.—The following are awarded: The Ashworth Hallett Scholarship, value £45, open to women only; two Martin Memorial Pathological Scholarships of £10 each; the Tibbits Memorial Prize, value 9 guineas, for proficiency in practical surgery; the Committee's Gold and Silver Medals for fifth-year students for general proficiency; the Augustin Prichard Prize, value about 6 guineas, for proficiency in anatomy; the Henry Clark Prize, value 11 guineas, for proficiency in gynæcology; the Crosby Leonard Prize, value 7 guineas, for proficiency in surgery; the Suple Surgical Prize, a gold medal and 7 guineas; the Suple Medical Prize, a gold medal and 7 guineas; the Henry Marshall Prize, value £12, for dressers; the H. M. Clarke Scholarship, value £15, for proficiency in surgery; the Sanders Scholarship, value £22 10*s.*, for general proficiency; the Barrett-Roué Scholarship for proficiency in diseases of the eye, ear, nose, and throat, value £14; Lady Haberfield Scholarship, value about 25 guineas; Phyllis Siepman Prize, for proficiency in Diseases of Children, value £25.

Bristol City Senior Scholarships and those offered by the counties of Gloucestershire, Somerset, Wilts, and Devon, are tenable in the University. Some of the Fellowships awarded by the Colston Research Society for research in the University are allotted to the Faculty of Medicine.

Post-graduate Study.—Qualified medical practitioners may be appointed as clinical assistants for a period of one or more months. They may act as assistants, if times permit, in more than one department and in any of the hospitals during their period of study. They will be entitled to the use of the clinical laboratories and medical library, and have the right to attend in all departments, including operations, post-graduate and ordinary clinical demonstrations, and post-mortem examinations. Demonstration courses with weekly lectures are held during May, June, and July.

All inquiries and applications for admission should be addressed to the Director of Post-graduate Studies (Clinical Section), Pathological Department, University of Bristol, who can be seen on any day by appointment.

Further information as to scholarships, curricula, and fees can be obtained from the Dean of the Faculty of Medicine or the Registrar of the University.

UNIVERSITY OF WALES.

This University has, inter alia, the privilege of granting Degrees in Medicine, and Diplomas in Public Health and Tuberculous Diseases. Preliminary courses of study for the Degrees in Medicine may be pursued at any of the constituent Colleges of the University—viz., at Aberystwyth, Bangor, Cardiff, or Swansea. The Welsh National School of Medicine is situated in Cardiff and is an integral part of the University College of South Wales and Monmouthshire there.

Particulars can be obtained on application to the Dean of the Faculty of Medicine, or to the Secretary, Welsh National School of Medicine, Newport-road, Cardiff. All classes are open to both men and women students.

ENGLISH MEDICAL CORPORATIONS GRANTING DIPLOMAS.

EXAMINING BOARD IN ENGLAND BY THE ROYAL COLLEGE OF PHYSICIANS OF LONDON AND THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

Under this heading we give the regulations for the examinations enjoined by the Conjoint Examining Board of the Royal Colleges of Physicians of London and Surgeons of England, and of the Society of Apothecaries upon students desiring their respective diplomas of qualification. We do not give any list of schools recognised by these bodies as eligible to prepare students for their examinations beyond mentioning that all the schools which we have already described (under the heading of the Universities to which they are attached) are recognised as suitable places of instruction by the corporations granting medical diplomas. The courses of study at the principal colonial medical schools are also recognised as qualifying for the examinations of these corporations.

Students are required to pass a Preliminary Examination in General Education recognised by the Board, and a *Pre-Medical Examination* in Chemistry and Physics conducted by the Conjoint Examining Board before commencing the five years curriculum of professional study or some other examination recognised by the Board—namely, the examination in Chemistry and Physics for the degree in Medicine of any University recognised by the Board; a Pre-Medical Examination conducted by any of the Qualifying Bodies whose Degrees or Diplomas are registrable on the Medical Register; the Higher School Certificates of Oxford and Cambridge Universities, and the Oxford and Cambridge Schools Examination Board; the Higher Certificates of London, Bristol, Durham Universities, the Joint Matriculation Board of the Northern Universities, and the Central Welsh Board Higher Certificate. A candidate must enter for Chemistry and Physics together, and he will not be allowed to pass in one without obtaining at the same time at least half the number of marks required to pass in the other subject. He will be admitted to the examination on producing evidence of having passed the required Preliminary Examination in General Education. The examination is partly written, partly oral, and partly practical. A candidate rejected in one or both subjects of the examination will not be admitted to re-examination until after the lapse of a period of not less than three months. The fee for the examination is £3 3*s.*, for re-examination in Chemistry £2 2*s.*, and for re-examination in Physics £1 1*s.*

There are two Professional examinations called the *First* and *Final Examinations*. The courses of study for these examinations may be commenced before the Pre-Medical examination in Chemistry and Physics or some equivalent examination has been passed, provided that three terms of study are completed after the examination has been passed.

The subjects of the First Professional Examination are: Section I. (*a*) Anatomy, including Histology and Embryology. (*b*) Physiology, including Biochemistry. Section II. Pharmacology, Practical Pharmacy, and Materia Medica. A candidate *must* have attended at a recognised Medical School courses of instruction in Anatomy, including Embryology, during five terms, during which he must have dissected the whole body, courses of instruction in Physiology, including General Biology, Biochemistry and Biophysics during five terms, courses of instruction in Pharmacology, Practical Pharmacy, and Materia Medica. A candidate may present himself for the two Sections together or separately, but he must take parts (*a*) and (*b*) of Section I. together until he has passed in one or both parts, but a candidate will not be allowed to pass in one part unless he obtains at the same time at least half the number of marks required to pass in the other part.

Section II. of the examination may be passed at any time before the candidate enters for the Final Professional Examination. The fee for the First Professional Examination is £10 10*s*., for re-examination after rejection in Section I. £6 6*s*., for re-examination after rejection in either part of Section I. £3 3*s*., for re-examination after rejection in Section II. £3 3*s*. A candidate who produces satisfactory evidence of having passed an examination in the subjects of Section I. or of either part of Section I. and of Section II. in the examination for the degree in Medicine conducted at a University recognised by the Board will be exempted from further examination in such subjects.

Final Professional Examination.—The subjects of the Final Professional Examination are: Section I. Pathology (including Morbid Anatomy, Morbid Histology, and Clinical Pathology), and Bacteriology. Section II. Part I. Medicine, including Medical Anatomy, Forensic Medicine and Public Health. Part II. Surgery, including Surgical Anatomy and the use of Surgical Appliances. Part III. Midwifery and Gynæcology. The examination is partly written, partly practical, partly clinical, and partly oral. A candidate may take Sections I. and II. and the three parts of Section II. of the Final Examination separately or may take the whole examination together. He will be required to produce the certificates required by the regulations before being admitted to the respective parts of the examination. A candidate who produces evidence of having passed an examination for a degree in medicine in the subjects of Pathology and Bacteriology at a University recognised by the Board is exempted from Section I. The fee for admission to Section I. is £4 4*s*.; for admission to Section II., Part I., £10 10*s*.; Part II., £10 10*s*.; Part III., £6 6*s*.; and the re-examination fees are respectively £3 3*s*., £6 6*s*., £6 6*s*., and £4 4*s*.

Students of recognised universities in England, Scotland, and Ireland, who have passed examinations for a degree in Medicine at their universities in the subjects of the First Examination of the Examining Board, may enter for a part of the Final Examination at the expiration of three years from the date of passing in Anatomy and Physiology on production of the required certificates.

Members of certain recognised Indian, Colonial, and Foreign universities who have passed examinations for the Degree of Doctor or Bachelor of Medicine or Surgery in the subjects of the First Examination may present themselves for the Final Examination under special conditions. The Board also grants Diplomas in Public Health, in Psychological Medicine, in Ophthalmic Medicine and Surgery, in Tropical Medicine and Hygiene, and in Laryngology and Otology. Candidates must hold a Medical qualification registrable in the United Kingdom or be Graduates in Medicine of a recognised Indian, Colonial, or Foreign University. *Particulars* and conditions of admission to all examinations, fees, &c., may be obtained from the Secretary of the Examining Board, Examination Hall, Queen-square, London, W.C. 1.

ROYAL COLLEGE OF PHYSICIANS OF *LONDON*:

THE MEMBERSHIP AND FELLOWSHIP.

The College confers two separate diplomas—the *Fellowship*, a purely honorary distinction, and the *Membership*, obtained by examination.

Membership.—The age for admission to this diploma, it will be noticed, has been changed from 25 to 23 years. The alteration in the by-law of the College is designed to enable men who have just finished house appointments to sit for an examination for which their recent clinical experience has exactly fitted them. The candidate must either have passed the examinations for the licence of the College, or else be a registered medical practitioner who has obtained the degree of Doctor or Bachelor of Medicine at a University recognised by the Censors Board. The examination is directed partly to pathology and partly to the practice of medicine. Credit is also given to candidates who show a knowledge of Latin, Greek, French, or German. Further information may be obtained from the Registrar at the College. The fee for admission as a Member of the College is 40 guineas, except when the candidate for membership is a licentiate of the College, in which case the fee already paid for the licence is deducted from the 40 guineas. The fee for the examination is 8 guineas, which is reckoned as part of the fee for admission in the case of success.

Fellowship.—The *Fellows* are selected annually from the ranks of the *Members* by the Comitia of the College.

ROYAL COLLEGE OF SURGEONS OF ENGLAND:

THE FELLOWSHIP.

The Royal College of Surgeons of England confers its diploma of Fellow upon a few distinguished persons in an honorary capacity. Two *Members of long standing* may also be elected to the Fellowship annually. But the bulk of the Fellows obtain the diploma as the result of examination.

Fellowship.—The examination for the Fellowship is divided into two parts—viz., the First Examination and the Second Examination. The subjects of the First Examination are Anatomy and Physiology, and those of the Second Examination are Surgery, including Surgical Anatomy and Pathology. The examinations are partly written and partly vivâ voce, and include the examination of patients and the performance of operations on the dead body. The First Examination will in future years be held in June and December and the Second Examination in May and November.

The fees for examination are: First Examination, first admission 8 guineas, and for each readmission 5 guineas. Second Examination, each admission 12 guineas. The fee payable on admission to the Fellowship by Members is 10 guineas and by non-Members 30 guineas, in addition to examination fees.

A Member of the College is admissible to the First Examination at any time after receiving his Diploma of Membership. A candidate who is not a Member is admissible after passing the First Professional Examinations of the English Conjoint Board in Anatomy and Physiology, or the equivalent examination in his University, on the production of certificates of attendance upon prescribed courses.

A Member of the College is admissible to the Second Examination at any time after having passed the First Examination, on producing evidence of having been engaged not less than six years in the study (or study and practice) of the profession.

A candidate who is not a Member of the College must possess the registrable surgical and medical degrees of universities recognised by the Council and must have been engaged in the study (or study and practice) of the profession for not less than four years subsequent to the date of obtaining the recognised qualification, one year of which shall have been spent in attendance on the Surgical Practice of a recognised hospital. The diploma of Fellow is not conferred upon successful candidates until they have attained the age of 25 years.

The Regulations may be obtained on application to the Secretary, Examining Board in England, Examination Hall, Queen-square, London, W.C. 1.

SOCIETY OF APOTHECARIES OF LONDON.

The Pre-Medical and Primary examination is held quarterly. Part I. includes Chemistry, Chemical Physics; Practical Chemistry; Materia Medica and Pharmacy. Part II. includes Anatomy, Physiology, and Histology. This examination cannot be passed before the completion of twelve months' Practical Anatomy with Demonstrations, and these subjects cannot be taken separately except in the event of the candidate having previously passed in one.

The Final examination is held monthly except in September. Part I. Clinical Surgery: Principles and Practice of Surgery, Surgical Pathology, and Surgical Anatomy, Operative Manipulation, Instruments, and Appliances. Part II. Clinical Medicine: Medicine, Pharmacology, Pathology, and Morbid Histology; Forensic Medicine, Hygiene, Theory and Practice of Vaccination; and Mental Diseases. *Part III. includes* Midwifery, Gynæcology, and Diseases of New-born Children and the Use of Obstetric Instruments.

The course of study for the *Final examination* includes attendance on the Surgical and Medical Practice, with Post-mortem Examinations, at a hospital connected with a medical school for a period of three winter and three summer sessions, including a course of Practical Midwifery, with attendance on 20 Midwifery cases. The course of medical study must extend over five years, and the office of dresser or clinical clerk must be held at a hospital or other institution recognised by the Society. Three academic years (33 months) must elapse after a candidate has passed the examination in Anatomy and Physiology before he can complete the Final examination.

Evidence shall also be given of practical instruction in Infectious Diseases and in Mental Diseases (at a lunatic asylum or in the wards of an institution containing a special ward set apart for the treatment of mental diseases), and in any two of the following subjects: Ophthalmic Surgery, Laryngology with Rhinology and Otology, Dermatology, and Diseases of Children. Candidates intending to present themselves for examination are required to give 14 days' notice. The fee for the Licence is 20 guineas. Female candidates are admitted to examinations.

Master of Midwifery.—This diploma has now been instituted and the first examinational session will be on Monday, Oct. 15th, 1928. Candidates will be admitted to the examination who have been registered practitioners for at least one year, and who have held a resident appointment in an institution recognised by the Society for six months or more, and who for three months have attended an antenatal clinic and an infant welfare centre, also recognised by the Society. Until 1932 practitioners of ten years' standing may enter for the examination without further formality than the production of satisfactory evidence that they have made a special study of the subjects. The examination will be conducted by written papers and by clinical and oral tests.

The entrance fee for the examination is £5 5*s.* and a further fee, which at present is fixed at £5 5s., will be paid before their admission to the Mastery, by those who have satisfied the examiners. Candidates for the first examination must send in their certificates before Oct. 1st to the Secretary of the Society, Mr. Frank Haydon, who will supply any other information.

The examination offices are open from 10 A.M. to 4 P.M.; on Saturdays from 10 A.M. to 1 P.M. All letters should be addressed to the Secretary, Court of Examiners, Society of Apothecaries of London, Blackfriars, E.C. 4.

PHARMACEUTICAL SOCIETY.

SCHOOL OF THE PHARMACEUTICAL SOCIETY OF GREAT BRITAIN (recognised by the UNIVERSITY OF LONDON).—The Pharmaceutical Society conducts examinations for registration as (*a*) Chemist and Druggist and (*b*) Pharmaceutical Chemist. For registration as Chemist and Druggist the candidate must pass (i) the Preliminary Scientific Examination (subjects Chemistry, Physics, and Botany); and (ii) the Chemist and Druggist Qualifying Examination (subjects Pharmacognosy, Pharmacy, Pharmaceutical Chemistry, and Forensic Pharmacy). Fee for each examination, 6 guineas; for each subsequent examination after failure, 4 and 6 guineas respectively. The Pharmaceutical Chemist Qualifying Examination (for registration as *Pharmaceutical Chemist*) includes Botany, Chemistry, Pharmacognosy, Pharmacy, and Forensic Pharmacy. Candidates must have passed the Preliminary Scientific Examination. Fee, 12 guineas; for each subsequent examination after failure, 6 guineas. Courses of Instruction are given for the Chemist and Druggist Qualifying Examination, and (two years' course) for the Pharmaceutical Chemist Qualifying Examination in conjunction with University College.

An Intercollegiate two years' course for the Final Examination for the degree of B.Pharm. of the University of London is also given in conjunction with University College. Medical students are admitted to the lectures and laboratory work in any or all the courses. Certificates of instruction in the School are received by the Conjoint Board of the Royal Colleges and by the University of London. Graduates in Science may carry out the research work necessary for the thesis for the Ph.D. of the University of London in the Society's Research Laboratories. Application for admission to the school, or for further information, may be made to the Dean, Prof. Greenish, 17, Bloomsbury-square, London, W.C. 1.

The *London College of Pharmacy for Ladies*, 7, Westbourne Park-road, W.2, which is under direct medical supervision, offers a nine months' course of instruction to women in preparation for the Apothecaries' Hall Diploma in dispensing.

METROPOLITAN CENTRES AFFORDING POST-GRADUATE FACILITIES.

Certain organisations and institutions provide for the needs of the medical student in his cirriculum and for the post-graduate student requiring special forms of instruction and opportunities for clinical observation. Many of the institutions are recognised by the English Conjoint Examining Board as a place of study for the fifth year of the curriculum.

Special Diplomas in public health, tropical, psychological, and ophthalmic medicine, medical radiology and electrology, laryngology, otology, and tuberculosis are now granted in proof of intensive work along the different lines indicated. Of these, the Diploma in Public Health, being regulated by the General Medical Council, is registrable. Appointments to and promotion in the various Services are largely dependent on the possession of a particular diploma, and each syllabus of the special courses available at the institutions which follow, either with or without association with the Fellowship of Medicine, is planned to afford the necessary instruction.

The Special Diplomas are dealt with fully on p. 420, where the connexion between the Bethlem Royal Hospital and the Maudsley Hospital and the Diploma in Psychological Medicine is referred to. Similarly the Hospitals of the Metropolitan Asylums Board provide post-graduate as well as under-graduate facilities, while the hospitals of the Seamen's Hospital Society both supply the instruction necessary for the Diploma in Tropical Medicine and Hygiene, and coöperate in the activities of the Fellowship of Medicine and Post-Graduate Medical Association.

HOSPITALS OF THE METROPOLITAN ASYLUMS BOARD. —These hospitals, of which there are 18 in the metropolis and the near vicinity, will shortly come under the administrative powers of the London County Council. The Board hold classes of instruction in fevers at all the infectious hospitals at which ordinary medical students attend, but the only hospital to which a class of instruction for the diploma in public health is attached is the North-Eastern Hospital. This course of lectures and demonstrations (three months) on clinical practice and in hospital administration is given at the North-Eastern Hospital, St. Ann's-road, Tottenham, N. 15, by the medical superintendent, on Mondays and Wednesdays at 4.45 P.M., and alternate Saturdays at 11 A.M., beginning Monday, Oct. 1st, 1928. This course complies with the requirements of the revised D.P.H. regulations of the General Medical Council. Application for further information should be made to the Clerk to the Metropolitan Asylums Board, Victoria Embankment, London, E.C. 4.

SEAMEN'S HOSPITAL SOCIETY.—The Society possesses seven establishments: the Dreadnought Hospital at Greenwich, 250 beds; the Albert Dock Hospital, E. 16, 53 beds; the Hospital for Tropical Diseases, Endsleigh-gardens, W.C. 1, 58 beds; Tilbury Hospital, Tilbury Docks, Essex, 80 beds; Queen Alexandra Memorial Hospital, Marseilles, 60 beds; King George's Sanatorium for Sailors, Bramshott, Hants, 80 beds; and the Angas Home, Cudham, 36 beds. Total, 617 beds. It has also a Dispensary in the East India Dock-road from which patients are transferred to the hospitals. In conjunction with the Fellowship of Medicine arrangements have been made for a course of operative surgery at the Dreadnought Hospital.

The London School of Hygiene and Tropical Medicine is located in the same building as the Society's Hospital for Tropical Diseases at 23, Endsleigh Gardens, Gordon-street, W.C., and the clinical teaching of the School is given in the Hospital (see p. 420).

THE FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.

Certain hospitals or groups of hospitals are working in conjunction with this Association, which has its office in the House of the Royal Society of Medicine, 1, Wimpole-street, W. 1. It provides intensive courses in general and special branches of medicine and surgery, which are arranged at short intervals, and also courses in special subjects the nature of which are indicated by the groups of hospitals coöperating in its teaching work. Demonstrations in clinical medicine, in surgery, and in ophthalmology are arranged also from October to July, and are open to all members of the medical profession without fee. Membership of the Fellowship is open to all qualified medical practitioners, the membership fee being 10*s.* per annum, which includes the subscription to the monthly *Post-Graduate Medical Journal.* Full information regarding the courses of study can be obtained from the Secretary.

GENERAL PRACTICE.

ROYAL NORTHERN GROUP OF HOSPITALS.—The Royal Northern Hospital, Holloway, London, N. 7, is the main institution of the Royal Northern Group of Hospitals, which includes the Royal Chest Hospital, City-road, E.C., Hospital of Recovery, Southgate, and the Reckitt Convalescent Home, Clacton-on-Sea. The total number of beds in the group is 400. Besides the honorary staff there are six anæsthetists, three pathologists, resident medical officer, resident house physician, three resident house surgeons, two resident casualty officers, and one resident obstetric surgeon. The large rectangular and circular wards, each of which contains 25 beds, the children's ward for children under 5 years of age, the observation wards in the new Casualty Department, the two operation theatres, and out-patient department are designed with a view of offering the greatest facilities for clinical work. The Special Departments include the following: Fracture, genito-urinary and neurological, physico-therapeutic, pathological (under a director of clinical pathology), tuberculosis, venereal diseases, and X ray (recently remodelled). Patients are removed to the Hospital of Recovery by ambulance a few days after operation. Demonstrations are given daily in the wards and out-patient departments. Clinical assistants (qualified), clinical clerks, and pathological clerks are appointed in the general and special departments and may receive certificates at the end of their terms of office. A new maternity department has been opened, and the light department has been re-equipped.

Weekly lectures by members of the hon. medical and surgical staff are free to all medical practitioners. Special classes and demonstrations are being arranged for post-graduates. They include instruction in general medicine and surgery, and also lectures and demonstrations in special subjects at the Royal Northern and Royal Chest Hospitals.

PRINCE OF WALES'S GENERAL HOSPITAL, Tottenham, N. 15.—This hospital is in the midst of a densely populated neighbourhood and contains medical, surgical, gynæcological, and children's wards, having 200 beds. There are special departments for gynæcological cases, diseases of the eye, ear, throat, and nose, skin diseases, plastic surgery, medical electricity, radiography, and dentistry. Operations are performed every afternoon of the week (except Saturday) at 2.30 P.M. Clinical instruction, ordinarily including laboratory classes, and lectures are given in the wards and out-patient departments, laboratories, and lecture hall in connexion with the North-East London Post-Graduate College attached. There are five resident medical officers, and clinical assistants are appointed under certain conditions. Special intensive post-graduate courses are also held at intervals throughout the year. Further particulars in regard to the hospital may be obtained from Dr. S. C. Shanks, Secretary to the Medical Committee, 87, Harley-street, W. 1; or from Mr. T. H. C. Benians, F.R.C.S., Dean of the College, at the Hospital.

WEST LONDON HOSPITAL, Hammersmith, W.—This hospital has 210 beds. Attached to the hospital is the West London Post-Graduate College. The practice of the hospital is reserved exclusively for qualified men. Instruction is given in the medical and surgical out-patient rooms and demonstrations are given in the wards. Clinical assistantships are obtainable in the various general and special out-patient departments. Special classes are held in Diseases of the Throat and Nose, Skin, and Eye, and in Gynæcology, Medical Electricity, Operative Surgery, Bacteriology, Anæsthetics, Intestinal Surgery, Medical and Surgical Diseases of Children, Blood and Urine, Clinical Microscopy, Cystoscopy, Venereal Diseases, and Operative Ophthalmology, Radiography, X Ray Therapy. The accommodation for post-graduates consists of a lecture room, together with reading, writing, and class rooms. The hospital has a fully equipped pathological laboratory, at which instruction is given in elementary bacteriology. The certificate of the hospital is accepted by the Admiralty, War Office, Colonial Office, and India Office in cases of study leave. Further information can be obtained on application to the Dean, Sir Henry Simson, at the Hospital. Secretary of the Post-Graduate College Mr. C. Cole, and of the Hospital Mr. H. A. Madge.

LONDON TEMPERANCE HOSPITAL, Hampstead-road, N.W. (Established 1873; Incorporated 1917.)—The hospital contains 135 beds. The medical and surgical practice of the hospital is open to students and practitioners. Operations: Monday, 1.30 P.M., Tuesday, 2.30 P.M., Wednesday, 9 A.M. and 1 P.M., Thursday, 8 A.M., Friday, 10 A.M. and 3 P.M., and Saturday, 9 A.M. New Out-patient Departments for special diseases have been opened: Neurology, Diseases of the Stomach and Disorders of Digestion, Diseases of Women, Genito-urinary Diseases, Diseases of the Rectum, and Dermatology.

HAMPSTEAD GENERAL AND NORTH-WEST LONDON HOSPITAL.—In-patient Department: Haverstock Hill, N.W.; Out-patient Department: Bayham-street, Camden Town (130 beds—viz., 102 free, 8 isolation and observation, &c., and 20 paying or contributory). Serves Hampstead and the populous districts of Kentish Town and Camden Town. The out-patients, with the exception of Hampstead casualty and emergency cases, attend exclusively at the Out-patients' Department, Bayham-street, Camden Town. Further particulars from the Secretary at the hospital. Post-graduate work is in connexion with the Fellowship of Medicine.

Queen Mary's Hospital, Stratford.—This hospital has developed from the West Ham and Eastern General Hospital. It has 200 beds and ministers to a very poor public. Founded as a dispensary in 1861, and developing into a hospital in 1890, steady extensions have been made during this century. A Royal Charter was obtained in 1917, and the hospital has become a valuable charity with a full medical staff of physicians and surgeons, and specialists for gynæcology, obstetrics, ophthalmological surgery, radiology, and dental surgery. The Fellowship of Medicine and Post-Graduate Medical Association makes frequent use of the opportunities here offered.

Particulars may be obtained from Major Raphael Jackson, Secretary, Queen Mary's Hospital, Stratford, E. 15.

NEUROLOGY.

The National Hospital, Queen-square, W.C.—The hospital, with the Convalescent Home at East Finchley and branch at Clapham Park, contains 265 beds and cots The out-patient physicians attend every Monday, Tuesday, Thursday, and Friday at 2 P.M., and the physicians daily. Clinical clerks are appointed under physicians and clinical assistants to out-patient physicians. Post-graduate Courses of Lectures and Demonstrations are held three times every year, usually commencing in January, May, and October, and lasting eight weeks. Special Courses in Neurological Ophthalmology, Neuropathology, and the Anatomy and Physiology of the Nervous System are given. The Pathological Laboratory is available for special work under the Pathologist.

West End Hospital for Nervous Diseases.—This institution is recognised by the University of London as a school of instruction in Neurology for the M.D. degree, Branch III., and for the D.P.M. The Out-patient Department is in Welbeck-street, W.; the In-patient Department is at Gloucester-gate, Regent's Park, and contains 80 beds. Completely equipped with pathological and other special departments, the hospital offers every facility for instruction in Neurological subjects. In conjunction with the Bethlem Royal Hospital, it offers courses of instruction for the D.P.M. Additional series of clinical demonstrations, apart from the general practice of the hospital, are held regularly each session. and the hospital coöperates with the Fellowship of Medicine in the programmes of special post-graduate teaching organised by the Association. Appointments as Hon. Clinical Assistants in the Out-patient Department are open to registered medical practitioners. The Savill Memorial Prize (value £15) and Medal are offered biennially for competition among post-graduate students who have attended the practice of the hospital or any special course. Full particulars may be obtained from Dr. C. C. Worster-Drought, Dean, or J. P. Wetenhall, Secretary, 73, Welbeck-street, W.

Hospital for Epilepsy and Paralysis, &c., Maida Vale, W. (85 beds).—Both in-patient and out-patient departments of this hospital are open free to students as well as to medical graduates. The out-patient department is open every week-day except Saturday at 2 P.M.

HEART AND LUNGS.

Hospital for Consumption and Diseases of the Chest, Brompton.—The hospital contains 333 beds. The Sanatorium at Frimley contains 100 beds and 50 beds for paying patients. Six house physicians reside in the hospital for a term of six months; their duties include attendance in the out-patient department. An additional month may be spent at the Sanatorium. Pupils are admitted to the practice of the hospital. Clinical Demonstrations are given throughout the year by members of the medical staff. Clinical assistants are appointed to the physicians *in the out-patient department* and clinical clerks to the physicians in the wards. The medical practice of the hospital is recognised by the English Conjoint Board and also by the University of London, the Apothecaries' Society, and the Army and Navy and Indian Medical Boards. The hospital is open to post-graduates and students. During the month previous to each conjoint *examination* the *teaching* will be as far as possible for students about to enter for the final examination. The hospital practice is open to post-graduate students.

Mount Vernon Hospital (Incorporated) for Tuberculosis and Diseases of the Lungs and Heart, Northwood; Central Out-patient Department, Fitzroy-square, W.—The hospital contains 150 beds, Medical and Surgical; 50 beds reserved for children requiring surgical aid. Clinical Demonstrations are given by the visiting Medical Staff at the hospital at Northwood. New departments for artificial light treatment have been opened both in the hospital and the *out-patient departments. Clinical assistants* are appointed to physicians in the wards and in the out-patient department.

City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E. 2.—Tuberculosis Dispensary (Boroughs of Bethnal Green and part Hackney). Special Departments: Surgical, Laryngological, Radiological, *Pathological, Electrocardiographic.* Assistants are appointed to the Clinics, and a limited number of research workers to the Pathological Department. The in-patient staff visit generally in the afternoon; out-patients at 2 P.M. The post-graduate students are admitted on payment of fees which entitle them to attendance at clinics, post-mortem demonstrations, *and operations.* Special demonstration and lecture courses are provided, and a club room. Graduates desiring Assistantships in any department should apply to the head of the Special Department.

National Hospital for Diseases of the Heart, Westmoreland-street, London, W. (founded 1857).—The practice of the hospital, both in the wards and out-patient department, is open daily to post-graduates and *others.* Systematic courses of instruction, with lectures and clinical demonstrations, are arranged during the winter and summer sessions; in addition an intensive course, of a fortnight's duration, takes place in January, July, and October of each year. The hospital is fully equipped with all the modern instruments for the investigation of the diseases of the Cardiovascular system, *and facilities* exist for those requiring practical instruction in Electrocardiography, X Rays, and other graphic methods. Clinical Assistants in the Out-patient Department are appointed from time to time.

DISEASES OF WOMEN AND CHILDREN.

Hospital for Sick Children, Great Ormond-street, W.C. 1. (contains 252 beds).—The practice is open to students of both sexes who have completed four years of medical study and also to qualified medical men and women. The medical staff are recognised by the University of London as teachers in Diseases of Children. Arrangements have also been made with University College Hospital and *the* London School of Medicine for Women for the routine admission of their students of both sexes to clerkships and dresserships in the wards. Appointments are made every three months to eight medical clerkships, which are open to students of the hospital. Clinical instruction is given daily by members of the visiting staff. Clinical Clerks are appointed once a month. In the pathological department facilities are afforded to post-graduates for obtaining theoretical and practical instruction in Clinical Pathology and Bacteriology, and in Medical Biochemistry in the Pathological and Biochemical Laboratories. Courses of eight to ten Lecture-Demonstrations are given at weekly intervals twice a year in both subjects

(Clinical Pathology and Bacteriology, and Biochemistry.) Time spent in clerking and dressing is recognised by the Universities of London, Oxford, and Cambridge, as well as by the English Conjoint Board as part of the final curriculum. These appointments are open to students of all recognised medical schools. In addition, special lectures in post-graduate work are held throughout each term of the year, as well as routine post-graduate instruction daily.

Queen Charlotte's Maternity Hospital (formerly Queen Charlotte's Lying-in Hospital) and Midwifery Training School, Marylebone-road, N.W.—This hospital receives over 2000 patients annually, besides having a large out-patient department. Medical pupils are received at all times of the year. Pupils have unusual opportunities of seeing obstetric complications and operative midwifery, on account of the very large number of primiparous cases—nearly one-half of the total admissions. Clinical instruction is given on the more important cases which present themselves. They also receive valuable instruction in the Antenatal Department, where over 4000 patients attend yearly. Special Lecture-demonstrations are given by members of the staff. Certificates of attendance at this hospital are recognised by all the Universities, Colleges, and licensing bodies. Pupil midwives and maternity nurses are received and specially trained. A Residential College provides accommodation for students and qualified practitioners (both men and women), and is opposite the hospital, with which it is in telephonic communication. Arrangements have been made for Medical Students to receive the preliminary instruction in Practical Midwifery recommended by the General Medical Council.

Royal Waterloo Hospital for Children and Women, Waterloo Bridge-road, S.E.—This hospital, founded at the date indicated by its title, has recently undergone considerable extensions, and has now 130 beds, while the latest buildings include a nurses' home and a new operation theatre. It has a full staff of surgeons, physicians, and gynæcologists, and also special departments. A new orthopædic department is in use, and a new nursing home is in occupation. The physiotherapeutic and electrical department has this year been extended and re-equipped. Particulars of post-graduate courses, which are held from time to time, can be obtained from the Secretary or from the Fellowship of Medicine.

Victoria Hospital for Children, Tite-street, Chelsea, S.W.—138 beds and a large out-patient department; the home at Broadstairs has 50 beds. Private wards in the Nurses' Home, named after H.R.H. Princess Mary (Viscountess Lascelles), at 29, Tite-street, adjacent to the hospital. Patients must be under the care of a consultant of one of the hospitals of London, and the question of payment for his fees is arranged between him and the child's parents. Application for admission should be made to the Secretary.

Queen's Hospital for Children (*late North-Eastern Hospital for Children*), Hackney-road, Bethnal Green, E.2.—For the sick children of the poor under 14 years of age. 134 beds in London and 36 at the seaside branch, "Little Folks" Home, Bexhill.—Special departments in Ear, Nose, Throat, Skin and Eye, and Dentistry. A radiologist attends four times weekly. There are massage and light departments, and a special whooping-cough physician. The practice of the hospital is open to students by arrangement with the medical staff, and post-graduate instruction in children's diseases, lectures and demonstrations are given at times notified by the Fellowship of Medicine.

Paddington Green Children's Hospital (46 beds).—This is a small hospital with a large out-patient department and a full staff, with eye, ear, skin, and dental departments. The facilities which it offers for observation of clinical practice are used by the Fellowship of Medicine.

Hospital for Women, Soho-square, W. (80 beds).—The teaching is available for post-graduates only, in limited numbers. Operations take place daily at 2 o'clock except on Saturdays. The X ray department is supplied with the latest installation both for diagnosis and treatment, and experience can also be gained in the treatment of malignant disease by means of radium. Incorporated is the London School of Gynæcology, comprising attendance in out-patient department, operating theatre, clinical lectures, and X ray treatment.

Samaritan Free Hospital for Women, Marylebone-road, N.W. (70 beds).—Qualified practitioners are admitted as clinical assistants to both the in- and out-patient departments. Full particulars in regard to fees may be obtained on application to the Secretary to the Medical Committee at the hospital.

East London Hospital for Children and Dispensary for Women, Glamis-road, Shadwell, E.—136 cots. Clinical instruction is given by the physicians and surgeons to the hospital to students in the fifth year of the curriculum. Two clinical clerkships for qualified or unqualified students are open every three months subject to reappointment if desired. Clinical assistants (qualified men only) are from time to time appointed in the out-patient department. Any additional information may be obtained on applying to the Secretary.

Chelsea Hospital for Women, Arthur-street, Chelsea, S.W.3.—This hospital has about 100 beds, and a certain number are reserved for patients paying £5 5s. a week and small fees to the surgeons for operations. There is a convalescent home of 32 beds at St. Leonards. There is a large out-patient department where the patients are seen at a nominal payment.

The Evelina Hospital, Southwark (76 cots), and The Belgrave Hospital, Clapham-road, also give facilities for the attendance of out-patient practice.

OPHTHALMOLOGY.

Royal London Ophthalmic Hospital (Moorfields, 1804–1899), City-road, E.C.—138 beds. The attendance at Moorfields Eye Hospital is now very large. Operations are performed daily from 10 A.M. to 1 P.M., and four surgeons attend on each day. Students are admitted to the practice of the hospital, and special courses of instruction are given, which extend over a period of five months, by members of the Surgical Staff, beginning in October and March. A composition fee entitles students to a perpetual ticket, and will admit them once to all the lectures and classes and to the examination for the hospital's full certificate. The instruction and classes are arranged so as to meet the requirements for the various diplomas in Ophthalmology, both the preliminary examination in Anatomy, Physiology and Optics, and those subjects required in the second part. Students of the hospital are eligible for the offices of house surgeon or clinical and junior assistants. Junior assistants are appointed every three months.

Royal Westminster Ophthalmic Hospital, Broad-street, Holborn, W.C. (84 beds).—This hospital has recently removed from its original site at Charing Cross to much larger premises, well adapted for teaching purposes. The clinics are held in the afternoons from 1 P.M. Operations are performed daily in the theatre at 3 P.M. Lectures and practical classes in the various branches of Ophthalmology, including Operative Surgery, Bacteriology, and Pathology, are held during the winter and summer sessions at 5 P.M. The practice of the hospital is open to both men and women practitioners, and medical students. Post-graduate students at the hospital are eligible for appointment as house surgeon, assistant house surgeon, refraction assistant (six appointments paid), and senior and junior clinical assistants.

ROYAL EYE HOSPITAL, St. George's-circus, Southwark, S.E.—There are 44 beds and 2 cots. Clinical instruction is given to students and post-graduates daily at 2.30 P.M., and Lectures, Demonstrations, and Laboratory Classes are arranged in preparation for examinations in Ophthalmology. Apparatus has been installed for the Microscopy of the Living Eye. Post-graduate students are eligible for appointment as Clinical Assistants and as Refraction Officers.

CENTRAL LONDON OPHTHALMIC HOSPITAL, Judd-street, St. Pancras, W.C.—This hospital has 40 beds, and clinical teaching is given daily. Classes of instruction in the use of the ophthalmoscope, with demonstrations on cases, and also classes on other subjects, to meet the requirements of the Conjoint Board for the D.O.M.S., and of the University of London for the M.S. in Ophthalmology, are given during the winter months, commencing in October. This school is recognised as a teaching institution by the Universities of London and Oxford, as well as the English Conjoint Board. It receives a portion of the pupils of the University College Hospital for the purposes of ophthalmic training. The Pathological and Bacteriological Laboratories have been rendered available for the use of any ophthalmic surgeons who desire to send specimens for examination. A small fee is charged for a report. A Clinical Demonstration *is held by members of the* staff at the Central London Ophthalmic Hospital at 5 P.M. *on the first Tuesday of every month.* Students of Medicine and Medical Practitioners are admitted *without fee.*

GENITO-URINARY AND VENEREAL DISEASES.

LONDON LOCK HOSPITAL AND HOME. (Founded 1746.)—In the institution at Harrow-road, W., there are 202 beds. In the male department and out-patient department in Dean-street, Soho, W., there are 38 beds. Male and female patients are seen at 91, Dean-street, Oxford-street, W.1, at any time from 9 A.M. until 9 P.M. daily. Intravenous injections are given at every clinic. Irrigations for males are given daily from 8 A.M. to 9 P.M. Female patients and children are seen daily at 283, Harrow-road, Paddington, W.9, from 9 A.M. until 8 P.M. Irrigations for females are given at any time. The hospital is linked up with the Fellowship of Medicine; special courses of lectures are held in May and November each year, and application for tickets should be made direct to the Secretary of the Fellowship. Only a limited number of practitioners and students are permitted to attend the practice of the Female Lock Hospital, and application should be made to Major Corbett (Dean) at the Male Lock Hospital, between the hours of 11 A.M. and 5 P.M., or to the Secretary at the Head office, 283, Harrow-road, W.9.

ST. MARK'S HOSPITAL FOR CANCER, FISTULA, AND OTHER DISEASES OF THE RECTUM, City-road, E.C.1. (Founded 1835.) (62 general beds and 10 private beds.)—For men and women. Operations are performed on Mondays, Wednesdays, and Thursdays at 2.30 P.M. Medical practitioners and students are invited to the operations and to the clinical instruction in the wards and in the out-patient department. Two fortnightly courses held during year in coöperation with the Fellowship of Medicine.

ST. PETER'S HOSPITAL FOR STONE AND OTHER URINARY DISEASES, Henrietta-street, Covent Garden. Established 1860. 30 beds for men and 2 beds for women and children.—The X ray department is diagnostic only. A loan of radium salts for research work was made by the British Empire Cancer Campaign in 1925. Medical practitioners and students are invited to the clinical instructions which are given in the wards and out-patient department daily, excepting that the only out-patient clinic open to medical women is that held at 2 P.M. Fridays for women and children, and to the operations in the theatre on Mondays at 2.30 P.M., and Wednesdays and Fridays at 2 P.M. *Post-graduate Courses of Lectures are arranged through the Fellowship of Medicine from time to time.*

ALL SAINTS' HOSPITAL FOR GENITO-URINARY DISEASES.—The in-patient department, 30 beds, is at *Finchley-road, and the terms of admission are* free or by payment according to means. The out-patient department in the Vauxhall Bridge-road provides clinical instruction through the Fellowship of Medicine.

ORTHOPÆDICS.

ROYAL NATIONAL ORTHOPÆDIC HOSPITAL, Great Portland-street, W. (200 beds.)—This institution is a good example of the fusion of small and scattered activities for the creation of an effective whole. The three orthopædic hospitals of the metropolis were combined for the formation of this central institution at the instance of the King's Hospital Fund, with the result that the grants from this Fund and the income from subscriptions can now be used to far better purpose and with economy. The hospital has also been approved by the Ministry of Health for the treatment of tuberculosis, the connexion between orthopædics and the therapeutics required in many forms of tuberculosis having become obvious. Country branch at Brockley Hill, Stanmore. (214 beds.)

EAR, NOSE, AND THROAT.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.—The hospital is open daily to all qualified medical practitioners on presentation of their visiting cards. Demonstrations of the cases and clinical instruction are given daily by the chief surgeon of each clinic. Lectures each Friday at 4 P.M. An intensive Course of Lectures with Operative Surgery Class, Peroral Endoscopy Class, and Pathology Class is given twice yearly—in May and October. Preparatory courses in Methods of Examination and Diagnosis at frequent intervals. Consultations on interesting cases take place on the fourth Wednesday in each month at 4 P.M. Clinical Assistants are appointed and are expected to hold office for at least three months. They are required to attend twice weekly at 1.30 o'clock for the afternoon, and at 4.30 o'clock for the evening clinics.

GOLDEN-SQUARE THROAT, NOSE AND EAR HOSPITAL (with which is amalgamated the London Throat Hospital, Great Portland-street).—Clinical instruction in the diagnosis and treatment of disease is given daily in the out-patient department from 2 to 5 P.M., and on Tuesdays and Fridays from 6.30 to 9 P.M. There is an annual out-patient attendance of over 50,000. Minor operations are performed on Mondays, Wednesdays, and Fridays, at 9.30 A.M. New wards and in-patient operating theatres have been opened recently, and the hospital now contains 73 beds. Practitioners and medical students are admitted to the practice of the hospital, and clinical assistants are appointed periodically.

METROPOLITAN EAR, NOSE, AND THROAT HOSPITAL. (Founded 1838.)—The hospital is in Fitzroy-square, W. The Out-patient Department is opened daily (Saturdays excepted) at 2.30 P.M. to all medical practitioners and senior students for acquiring clinical instruction and technical knowledge. Operations upon in-patients are performed on Tuesdays, Wednesdays, and Thursdays at 10 A.M. Clinical Assistants are appointed as vacancies occur, and have responsible duties.

SKIN.

LONDON SCHOOL OF DERMATOLOGY, ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, 49, Leicester-square, W.C.—In-patient Department (33 beds) at 262, Uxbridge-road, W. Out-patient Clinics are held daily at 2 and 6 P.M. (Saturdays 2 P.M. only), when demonstrations are given on the cases presenting themselves. *The Chesterfield Lectures,* constituting a systematic course in dermatology, are given on Tuesdays and Thursdays at 5 P.M., from October to

March, by the hon. medical staff of St. John's Hospital and the physicians in charge of the Dermatological Departments of the London Teaching Hospitals. The lectures are free to those attending the practice of the hospital and to registered medical students. At the end of the course an examination is held for the Chesterfield Medal in Dermatology, and is open to those who have attended three-quarters of the lectures. The Electrical Department is open daily from 2 to 4 P.M., except on Wednesdays and Saturdays. Laboratory Courses in the Pathology and Bacteriology of the Skin can be arranged.

THE LONDON SKIN HOSPITAL (Fitzroy-square), and the HOSPITAL FOR DISEASES OF THE SKIN (Blackfriars-road), admit students to their practice, which is among out-patients.

CENTRES OUTSIDE LONDON AFFORDING EDUCATIONAL FACILITIES.

Nearly every hospital of a general character in the country having more than 150 beds falls within this category, and certain of them have already been noticed in connexion with the universities to which their clinical practice is attached.

The following alphabetical list includes the provincial hospitals which are recognised by the English Conjoint Board for a part of the required training in medical and surgical practice through clerkships and dresserships.

BATH ROYAL UNITED HOSPITAL, Bath.—This hospital contains 212 beds, 72 of which are situated in Combe Park, Bath, and are for *paying patients* only, and possesses X Ray, Massage, Bacteriological Departments, a Pathological Laboratory, and a fine library. Secretary: Mr. J. M. Sheppard. V.D. Clinics are held on Tuesdays (for women), and on Fridays and Saturdays (for men), at 5 P.M., and Ear, Throat, and Nose Clinics on Thursdays, at 4 P.M.

BEDFORD COUNTY HOSPITAL, Bedford.—This hospital has 111 beds, including 15 beds in the paying wards, X Ray and Pathological Departments. There is in connexion with the institution a convalescent home (20 beds) at Aspley Heath, nr. Woburn Sands. The hospital is approved by the University of London for the M.D. and M.S. Examinations. Secretary: Mr. Beauchamp Wadmore.

BRADFORD ROYAL INFIRMARY, Bradford.—This hospital contains 215 beds and, in addition, has 50 recovery beds at the Woodlands Convalescent Home, Rawdon. There are 4 Honorary Consulting Physicians, 1 Honorary Consulting Surgeon, 1 Honorary Consulting Laryngologist, 1 Honorary Consulting Gynæcologist, 1 Honorary Consulting Pathologist, and 1 Honorary Consulting Dental Surgeon. The Acting Staff consists of 3 Honorary Physicians, 4 Honorary Surgeons, 1 Honorary Radiologist, 1 Honorary Laryngologist, 1 Honorary Ophthalmic Surgeon, 1 Honorary Dental Surgeon, 2 Honorary Assistant Physicians, 2 Honorary Assistant Surgeons, 1 Honorary Assistant Radiologist, 5 Anæsthetists, 1 Pathologist, 1 Resident Surgical Officer, 1 House Physician, and 4 House Surgeons. The material passing through the *surgical* wards consists of major operations, chiefly abdominal and gynæcological work, and affords excellent facilities for either students or post-graduates. There are special clinics for Orthopædic cases and for electrotherapeutic and sunlight treatment. Plans for a new hospital of 360 beds with an additional self-contained block for 70 paying patients have been adopted and building operations have commenced. *Secretary-Superintendent*: Mr. J. J. Barron.

COVENTRY AND WARWICKSHIRE HOSPITAL, Coventry (established 1810).—There are 307 beds available at this hospital at the present time. At the beginning of this year a large house and extensive grounds, situated about 3½ miles from the centre of the city, were purchased, which will be opened at the end of the year as an annexe to the hospital. The building is to be styled the "Alcock" Convalescent Hospital, and will provide for at least another 40 patients. At the main hospital there are separate Medical, Surgical, Maternity, Children's and Accident Wards, also a separate Ophthalmic Block complete with its own theatre. There are separate departments and clinics for Ear, Nose and Throat Diseases; X Ray, Electrical and Sunlight treatment; also V.D. clinics. An up-to-date Pathological Laboratory was *opened early in the year*, and a second general operating theatre.

DERBYSHIRE ROYAL INFIRMARY, Derby.—This is a General Hospital containing 336 beds. It was founded in 1810, and was entirely rebuilt in 1892–94. In recent years there have been numerous alterations and additions to keep pace with modern requirements. The Hospital is built on the pavilion system and provides, in addition to the usual Medical and Surgical blocks, a separate Ophthalmic block of 40 beds, a separate Children's block of 34 beds (Medical and Surgical), Gynæcological Wards, and an Ear, Throat, and Nose Department. There is a large and well-equipped Out-patient Department, also separate Orthopædic, X Ray, Electrical, Pathological, and Venereal Diseases Departments. The Honorary Visiting Staff consists of 2 Honorary Physicians, 3 Honorary Surgeons, 1 Honorary Ophthalmic Surgeon, 1 Honorary Gynæcologist, 1 Honorary Assistant Physician, 1 Honorary Assistant Surgeon, 1 Honorary Pathologist, and 2 Honorary Surgeon Dentists. The salaried Medical Staff consists of a non-Resident Staff of 1 Surgeon-in-charge of X Ray and Electrical Departments, 1 Surgeon-in-charge of Venereal Diseases Department, 3 Anæsthetists, and a Resident Staff of 4 House Surgeons, 1 House Physician, and 1 Assistant House Surgeon and Casualty Officer. Registered Medical Students are admitted to witness the medical and surgical practice on payment of fees. Superintendent and Secretary: Mr. Walter Banks, F.C.I.S.

GLOUCESTERSHIRE ROYAL INFIRMARY AND EYE INSTITUTION, Gloucester.—This hospital, which was granted the title of "Royal" on the occasion of King Edward VII.'s visit to Gloucester in the year 1909, has 140 beds. Secretary: F. J. Symons. An electrical and massage department has been established and venereal clinic opened. Also ear, nose, and throat department, X ray department, ultra-violet ray department, orthopædic department, dental department, and pathological laboratory.

HULL ROYAL INFIRMARY, Hull.—This hospital contains 267 beds, and since its establishment in 1782 has undergone steady additions and improvements, including up-to-date Ophthalmic, Radiological Nose, Throat and Ear, Dental, V.D., Violet Rays and Pathological Departments. Recent extensions include a new Operating Theatre, Nurses' Home, and extensions to the old X Ray, Electrical, and Out-patient Departments. Work is in progress on the erection of a block of 100 beds, being the first instalment of a new 500-bed hospital which it is proposed eventually to build on a site which has been given the the Infirmary at Sutton-on-Hull. The Honorary Staff consists of 2 Consulting Physicians, 3 Consulting Surgeons, 2 Consulting Ophthalmic Surgeons, 3 Physicians, 4 Surgeons, 1 Ophthalmic Surgeon, 1 Aural Surgeon, 1 Radiologist, 1 Pathologist, 2 Assistant Physicians, 2 Assistant Surgeons, 1 Assistant Ophthalmic Surgeon, 1 Assistant Aural Surgeon, 1 Dental Surgeon, 1 Assistant Dental Surgeon, 4 Anæsthetists, 1 Officer-in-charge of V.D. Department. Resident Staff: 1 House Physician, 1 House Surgeon, 1 Assistant House Physician, 2 Assistant House Surgeons, 1 Assistant Surgeon to Special Departments, 1 Casualty Officer. An annexe at Withernsea has accommodation for 30 patients.

KENT AND CANTERBURY GENERAL HOSPITAL, Canterbury.—The hospital contains 120 beds. Pupils of the staff are admitted to the practice of the hospital. Operations daily. There is an Ophthalmic Department with two wards for in-patients, a Venereal Clinic, an Orthopædic, Massage, and Electrical Department, and Actinotherapeutic Department. Secretary: Mr. W. T. Southwood.

Leicester Royal Infirmary, Leicester.—At the *General Infirmary* there are 333 beds, and at the *Children's Hospital in connexion*, 70; venereal diseases, 17; total 420 beds. A reconstruction scheme has been carried out, and £250,000 spent on bringing the accommodation of the institution to a modern standard of efficiency. This scheme has included the provision of two modern operating theatres, two new wings, and self-contained out-patients' department. The Children's Hospital has been reconstructed and enlarged by the addition of a third ward at a cost of £14,500. Pathological Laboratories and post-mortem rooms were rebuilt at a cost of £11,000, also an orthopædic out-patient department at a cost of £9500, £5000 of which was provided by the Freemasons of the province as their war memorial. The Nurses' Home has recently undergone enlargement by 60 bedrooms, and now provides for 160 nurses and staff. The 150th anniversary of the Institution has recently passed, and a sum of £100,000 was raised in commemoration. Important and extensive improvements are (1928) being carried out. An old central wing erected in 1861 is being replaced by a new wing of three wards, at a cost of £48,000. Other structural improvements are being effected at a cost of £25,000, comprising reconstruction of the kitchens, new temporary ward of 30 beds, and a new venereal disease department. There are ten resident salaried medical officers—viz., four house surgeons, two house physicians, two anæsthetists, and two dressers. Most of the posts are filled half-yearly and afford exceptional opportunities for post-graduate experience and senior students. Dressers are given an honorarium. A post-graduate course of lectures is arranged annually by the Leicester Medical Association, and also clinical classes are held for graduates preparing for M.D. and M.R.C.P. New accommodation for resident medical officers has been erected.

Norfolk and Norwich Hospital, Norwich.—This hospital has at present 338 beds. There is a convalescent home with accommodation for 35 patients at Cromer. The Honorary Medical and Surgical Staff consist of 2 Consulting Physicians, 3 *Consulting* Surgeons, 1 Consulting Radiologist, 1 Consulting *Ear, Nose and Throat* Surgeon, 3 Physicians, 3 Surgeons, 1 Assistant Physician, 3 Assistant Surgeons, 1 Surgeon, Ear, Nose and Throat Department: 2 Ophthalmic *Surgeons*, 1 Radiologist, 1 Pathologist and 2 Dental *Surgeons*. There are 3 Honorary Anæsthetists and Honorary Assistants to the Ear, Nose and Throat Department, the X ray Department, Ophthalmic Department, and Cardio-Vascular Clinic. Other medical officers are: 1 Assistant Pathologist and 1 Assistant to the Venereal Diseases Department. The Resident Medical Staff consists of 1 House Physician, 3 House Surgeons, 1 House Surgeon to the Ear, Nose, Throat, and Eye Department, and 1 Casualty Officer. A private patients' home has recently been opened. Students are admitted to the practice of the *Hospital* for a fee of £5 5s. for six months. House Governor and Secretary: Mr. Frank Inch.

Northampton General Hospital, Northampton.—Two new wings were opened in 1904 and the old buildings entirely renovated and rearranged. In 1926 a new isolation block of 30 beds was opened. The number of beds is 230. *Non-resident* pupils receive and have every opportunity of *acquiring a* practical knowledge of their profession Pupils can be received at any time. There is an up-to-date Pathological Laboratory: also X Ray and Therapeutic Department and V.D. Clinic.

North Staffordshire Royal Infirmary, Hartshill, Stoke-on-Trent.—The New Infirmary, opened in 1869, is built on the pavilion plan, has accommodation for about 316 patients, *including* Children's wards, a Bacteriological and Pathological department, and a department for the treatment of Diseases of the Eye, X Ray and Electrical department (including Ultra-Violet Ray Lamps); Cardiographic department, a department for the treatment of Diseases of the Ear, Nose, and Throat, an Orthopædic department, an Electrocardiograph department, and Venereal Diseases clinics; so that there are excellent facilities for acquiring a practical knowledge of the profession. During the last four years the sum of £170,000 has been spent on new buildings and alterations. The extensions comprise a new ward block also containing new X Ray and Orthopædic departments with connecting corridors to the existing Infirmary, large extensions to the nurses' home, a new boiler house, new chimney stack, and a new laundry. The whole institution is now equipped thoroughly. Secretary and House Governor: Mr. W. Stevenson.

Nottingham General Hospital.—There are at this hospital 357 beds available for medical and surgical patients, and 54 beds are in the detached branch known as "The Cedars" Branch of the General Hospital. The Medical and Surgical Staffs consist of 1 Honorary Consulting Physician, 2 Honorary Consulting Surgeons, 1 Honorary Consulting Physician in Venereal Diseases, 3 Honorary Physicians, 4 Honorary Surgeons, 2 Honorary Assistant Physicians, 2 Honorary Assistant Surgeons, 2 Honorary Aural Surgeons, 1 Honorary Dermatologist, 2 Honorary Anæsthetists, 2 Honorary Assistant Anæsthetists, 1 Honorary Surgeon Dentist, 1 Honorary Medical Officer in Charge of X Ray and Electro-therapeutic department, and 1 Pathologist. The Resident Medical Staff consists of 2 House Physicians, 4 House Surgeons, 1 Aural House Surgeon, and 1 Casualty Officer. The special departments are the Ear, Nose and Throat, Skin, Dental, Massage and Exercise, X Ray, Orthopædic, Electrotherapeutic, Ultra-Violet Light. *House Governor and Secretary*: Mr. P. M. MacColl.

Royal Berkshire Hospital, Reading.—This hospital, which *contains* 237 *beds*, was enlarged in 1912, and includes an Out-patient Department, a Casualty Department, an X Ray Department, Electrotherapeutic and Massage Department, an Orthopædic Department, a V.D. Clinic, a Laboratory, an Eye Theatre, Eye Wards, a Maternity Ward, and two Motor and one Horse ambulances. The hospital is approved by the General Nursing Council as a Training School for Nurses. Post-graduate Lectures are given, and by the Ministry of Health for V.D. Treatment.

Royal Devon and Exeter Hospital, Exeter.—The hospital contains 225 beds (including special children's wards) and has a good library, museum post-mortem room, and pathological laboratory. Attendance on the practice of this hospital qualifies for all the examining boards. There is also a Private Nursing Staff attached to the hospital. For particulars as to fees, &c., apply to the Matron. A new wing was added in 1897 and the "Victory" wing for the treatment of discharged disabled soldiers and sailors completed and opened in 1922. Arrangements may be made by which gentlemen in practice desiring to increase their qualifications may have the use of the museum and library and other facilities and by which students may attend midwifery. A new Operating Theatre was opened *in* 1906 (the gift of Mrs. Nosworthy of Dawlish, Devon). The Electrical Treatment Department (the gift of Mrs. M. A. Sanders) was opened in 1907 by Lady Duckworth-King. This department was enlarged in 1925 to meet the ever-increasing work, and now forms *one of the most* important sections of the hospital. A department was opened in 1917 for the treatment of genito-urinary diseases; there are three sessions per week, two *for men* at 3 P.M. and 7 P.M., and one for women at 3 P.M.

Royal Hants County Hospital, Winchester.—158 civilian beds. Secretary: Mr. Herbert Maslen.

Royal Hospital, Portsmouth.—180 beds. There are X Ray and Massage Departments.

Royal Salop Infirmary, Shrewsbury.—This hospital has 150 beds. In-patients, 1565; out-patients, 1448; out-patients' attendances, 21,387; accidents and casualties, 3540; dental cases, 288. Secretary-Superintendent: J. W. Noble. A New Wing for the reception of Women and Children, capable of accommodating some 40 patients, has now been erected.

Royal South Hants and Southampton Hospital, Southampton.—This hospital contains 130 beds, but will be increased to 214 beds within the next few months, with every facility for clinical instruction. Special Departments: Ear, Nose, and Throat; X Ray; Massage and Electricity; Ultra-Violet Ray; Venereal Diseases. Large Out-patient Department.

Royal Sussex County Hospital, Brighton (225 beds).—This hospital affords ample facilities for students, possessing a large out-patient department, including Ophthalmic, Dental, Dermatological, Gynæcological, X Ray, and Orthopædic sections, and a well-appointed clinical research and bacteriological department. The hospital does not take resident pupils, but out-pupils may attend the practice of the hospital for any period not exceeding two years, on payment in advance of a fee, not exceeding 20 guineas, as the Board of Management shall direct.

Salisbury General Infirmary, Salisbury.—This hospital contains 142 beds. Maternity and antenatal and ophthalmic wards; maternity and child welfare clinic.

South Devon and East Cornwall Hospital, Plymouth.—This hospital has 185 beds (including 10 for venereal diseases in a separate building). Special departments include Pathological, X Ray, Deep-Therapy, Cardiographic, Ultra-Violet Rays, Electrotherapeutic, and Orthopædic: also medical and surgical out-patients. Pensioners are received as in-patients, and are also treated as out-patients.

Staffordshire General Infirmary, Stafford (established 1766).—This hospital has 100 beds.

West of England Eye Infirmary, Exeter.—64 beds. Students of the Exeter Hospital can attend the practice of the Eye Infirmary. A ward is set aside for newly-born babies suffering from infectious eye diseases. Mothers with babies are accommodated.

Wolverhampton and Staffordshire Hospital, Wolverhampton (210 beds).—Special departments for Children, Infectious cases, Gynæcology, Ear, Throat, and Nose Diseases, Electrotherapeutic and X Rays, Orthopædics, Artificial Sunlight, Venereal Disease, Pathological Laboratory, Dentistry, and Electrocardiographic Installation. There is an excellent library. The resident officers are a resident surgical officer, resident medical officer, two house surgeons, and resident anæsthetist. Pupils are allowed to witness the whole of the practice of the hospital and to be present at operations and have every opportunity of acquiring a practical knowledge of their profession. A course of Practical Pharmacy is given by the dispenser. Fees on application. Applications should be made to the Honorary Secretary of the Medical Committee.

Worcester General Infirmary, Worcester.—This hospital has 132 beds. Pupils are taken by members of the Honorary Medical and Surgical Staff. New X Ray and Electrical and Wolfram Arc Light, Ear, Nose and Throat, and Orthopædic Departments have been erected and are now in use. Additional accommodation for the Honorary Staff and Out-patients and also an Outdoor Shelter in connexion with the Children's Ward have been built as a memorial to King Edward VII., and fire-escape staircases erected.

York County Hospital, York.—This hospital contains 180 beds. There are balconies for outdoor treatment, two installations of X ray apparatus, electrotherapeutic and massage department, actinotherapy installation, Zünd-Burguet apparatus for treatment of chronic deafness, and clinical laboratory. A Venereal Diseases Clinic is held.

These hospitals vary much in size and scope, and obviously offer, for reasons of geography, many separate appeals, so that no detailed information upon any particular points in reference to any particular institution would be of service to any large group of students. It is unnecessary to point out to the general practitioners in the neighbourhood the advantages to be obtained from the post-graduate facilities offered to them by the hospital in their midst, and it is gratifying to know that a far wider use is being made of these facilities than was formerly the case.

Medical students completing their curriculum by attendance at authorised courses in these hospitals must ascertain, by communication with the Secretary, information concerning fees and other details.

II.—SCOTLAND.

THE UNIVERSITIES.

UNIVERSITY OF EDINBURGH.

Four Degrees in Medicine and Surgery are conferred by the University of Edinburgh—*viz.*, *M.B.*, *Ch.B.*, *M.D.*, and *Ch.M.* The degree of *Ch.B.* shall not be conferred on any person who does not at the same time obtain the degree of *M.B.*, and the degree of *M.B.* shall not be conferred on any person who does not at the same time obtain the degree of *Ch.B.* No one is admitted to the degrees who has not been engaged in Medical and Surgical study for five years

Candidates for the degrees of M.B. and Ch.B. must have attended for at least three academic years the medical and surgical practice either of the Royal Infirmary, Edinburgh, or of a general hospital elsewhere which accommodates not fewer than 80 patients and possesses a distinct staff of physicians and surgeons. They must have attended courses of instruction in Clinical Surgery and Clinical Medicine each of nine months, and courses of instruction in all the subsidiary subjects. They must have attended a course of instruction in Clinical and Practical Midwifery and have personally conducted 12 cases of labour.

With respect to the places and institutions at which the studies of the candidate may be prosecuted the following regulations have effect:—Three of the five years of medical study must be spent in the University of Edinburgh. The remaining two years may be spent in any University of the United Kingdom, or in any Indian, Colonial, or Foreign University recognised for the purpose by the University Court, or in such medical schools or under such teachers as may be recognised for the purpose by the University Court.

Women are admitted to graduation in medicine under the same conditions as men.

Bachelors of Medicine and *Bachelors of Surgery* may proceed to the degrees of *Doctor of Medicine* and *Master of Surgery* after they have spent one year in the medical or surgical wards respectively of a hospital, or the Military or Naval Medical Services, or in scientific work bearing directly on their profession, or two years in practice. In each case an examination must be passed and a thesis submitted for approval of the Faculty.

Post-graduate Instruction.—The University takes part in the Courses given under the auspices of the Edinburgh Post-graduate Courses in Medicine. In the departments of the Faculty of Medicine provision is made for research by students of graduate standing. In the University laboratories facilities will be provided for candidates for the Degree of Ph.D. whose applications to engage in research have been accepted by the Senatus.

In connexion with the University and Royal Colleges Post-graduate Instruction is given each year, chiefly in the Summer Vacation (July–September). Special Courses are arranged for, and particulars may be had on application to the Hon. Secretary, Post-graduate Courses in Medicine, University New Buildings, Edinburgh.

The University of Edinburgh is especially rich in scholarships and prizes in medical subjects. Full particulars concerning these, as well as concerning the fees at different stages, can be obtained from the Dean of the Medical Faculty.

ROYAL INFIRMARY, Edinburgh.—994 beds, including 42 cots for children. The clinical work of the Edinburgh student is done at the Royal Infirmary. Courses of Clinical Medicine and Surgery are given by the physicians and surgeons to male and female students. Special instruction is given on Diseases of Women, Physical Diagnosis, Diseases of the Skin, Diseases of the Eye, the Ear, the Larynx, and the Teeth. Separate wards are devoted to Venereal Diseases, Diseases of Women, Diseases of the Eye, the Ear, Throat and Nose, and the Skin, and also to cases of Incidental Delirium or Insanity. There is also a large and complete Radiological Department. Post-mortem examinations are conducted in the anatomical theatre by the pathologist and his assistants, who also give practical instruction in Pathological Anatomy and Histology.

The appointments are: 1. Resident physicians and surgeons are appointed and live in the house free of charge. The appointment is for six months, but may be renewed at the end of that period by special recommendation. 2. Non-resident house physicians and surgeons and clinical assistants are appointed for six months. The appointment may be renewed for a like period by special recommendation. 3. Clerks and dressers are appointed by the physicians and surgeons. These appointments are open to all students and junior practitioners holding hospital tickets. 4. Assistants in the Pathological Department.

Facilities are given in connexion with the Post-graduate Courses arranged by the Edinburgh University and the two Royal Colleges jointly.

ROYAL HOSPITAL FOR SICK CHILDREN, Sciennes-road, Edinburgh.—120 beds, and fitted with every modern improvement. A fully equipped out-patient department (medical and surgical) is conducted daily. Systematic courses of instruction, which qualify for graduation in the Edinburgh University and elsewhere, are given thrice throughout the year by the staff. Each course consists of 50 meetings and combines *medicine* and surgery. Post-graduate Courses of Lectures are held during the summer *vacation*. Full particulars with regard to teaching can be obtained from the Dean's office, University New Buildings, Edinburgh.

EYE, EAR, AND THROAT INFIRMARY OF EDINBURGH (with which is incorporated the Edinburgh Eye Dispensary), 6, Cambridge-street, Lothian-road.—Clinical Lectures and Instruction are given in this institution, which is open at 1 o'clock daily for out-door patients for Eye Diseases; Mondays, Thursdays, and Saturdays at 12 noon, and Tuesdays and Fridays at 4 P.M. for outdoor Ear, Nose, and Throat Patients. Patients whose diseases require operations or extra care are accommodated in the house (10 beds). Practical Ophthalmoscopic Classes may be arranged, and Clinical Assistants are appointed from time to time. A Post-graduate Course in *Diseases of the* Ear, Nose, and Throat is held each academic term, commencing in May, October and January, and continuing for six weeks. The next course commences in October. The class meets at 5 P.M. on Tuesdays and Fridays, and the instruction, which is practical, is supplemented by lantern demonstrations. Full particulars from the Secretary, 32, Charlotte-square.

UNIVERSITY OF GLASGOW.

The University of Glasgow is both a teaching and a degree-granting body, but admits to graduation only candidates whose preliminary examination and course of study conform to its own regulations. Within certain limits instruction given by recognised medical schools and teachers may be accepted, but not less than one-half of the subjects other than clinical must be taken in this or some other recognised university, and at least two years of the course must be taken in Glasgow University. Seven degrees, open both to men and women, are conferred: *M.B.* and *Ch.B.* (always conjointly), *M.D.* and *Ch.M.*; *B.Sc.* in Public Health; *D.Sc.* in Public Health; *B.Sc.* in Pharmacy; and *Ph.D.* in the Faculty of Medicine. A Diploma in Public Health (*D.P.H.*) is also granted.

All information as regards the extent and standard of the Preliminary Examination may be obtained by application to the Secretary, Scottish Universities Entrance Board, 81, North-street, St. Andrews.

For the degrees of M.B. and Ch.B. a curriculum of five years is required. The candidate must attend a course or courses of instruction in each of the following subjects of study, extending over not less than the number of terms specified in each case, and including such class examinations as may be prescribed in connexion with the several courses:—Chemistry (including Organic Chemistry), two terms; with Practical Chemistry, one term; Physics (with practical work), one term; Botany (with practical work), one term; Zoology (with practical work), one term; Anatomy and Practical Anatomy, five terms; Physiology and Practical Physiology, three terms; Materia Medica and Therapeutics (together or separately), each subject, one term; Pathology and Practical Pathology, three terms; Medical Jurisprudence and Public Health (together or separately), each subject, one term; Midwifery and Diseases peculiar to Women and to Infants, two terms; Surgery, two *terms*; Medicine, two terms. Candidates must attend for at least three years the Medical and Surgical Practice of a recognised hospital accommodating at least 80 patients and having a distinct staff of physicians and surgeons. At least nine months' hospital attendance is required on both Clinical Surgery and Clinical Medicine with nine months more of general hospital practice: the student must have acted for six months as clerk in medical and dresser in surgical wards, and must have had six months' outdoor practice; he must also have *attended a course* of Mental Diseases and of Practical Pharmacy (25 meetings), must have been properly *instructed* in Vaccination at a public vaccination station, and must have attended at least 20 *cases* of labour and the Practice of a Lying-in Hospital. The University also requires further study in various special subjects: Ophthalmology, Diseases of the Ear, Diseases of the Throat and Nose, Venereal Diseases, Tuberculosis, Fevers, *Vaccination*. The *final* year consists of three intensive terms of study one devoted to Midwifery and Diseases of Women, one to Surgery, and one to Medicine.

There are four Professional *Examinations*, the first comprising Botany, Zoology, Physics, and Chemistry; the second comprising Anatomy and Physiology; the third comprising Materia Medica and Therapeutics and Pathology; and the fourth or final, comprising Medical Jurisprudence and Public *Health*, Surgery and Clinical Surgery, Practice of Medicine and Clinical Medicine, and Midwifery and the Diseases Peculiar to Women and to Infants.

The degrees of M.D. (Doctor of Medicine) and Ch.M. (Master of Surgery) are granted to candidates, not under 24 years of age, who have previously obtained the double bachelorship on completing examinations, in Clinical Medicine for M.D. and in Surgical Anatomy, operations on the dead body, and *Clinical* Surgery for Ch.M. The higher degree of Doctor of Philosophy (*Ph.D.*) is also conferred *in* the Faculty of Medicine. Candidates must already have obtained a degree (or equivalent diploma) from an approved University or College and must prosecute a course of special study or research for two or three years and given evidence of satisfactory progress. A thesis must be presented for approval by the Senate on the recommendation of a Special Committee. The candidate may be required to undergo an oral or other examination on the subject matter of the thesis.

Post-graduate Medical Teaching is available under the auspices of Glasgow Post-Graduate Medical Association, which is representative of practically all the Teaching Institutions in Glasgow. Weekly demonstrations for practitioners are given throughout the winter and spring, and comprehensive courses of instruction during the summer and autumn. There is a General Medical and Surgical Course during the last two weeks of August and the first two weeks of September. This is a whole-time course and includes most of the subjects of interest to the general practitioner. The forenoons are occupied with General Medicine and Surgical Diagnosis and Minor Surgery in the Royal Infirmary and in the Victoria Infirmary. In the afternoons special subjects are dealt with in some of the special hospitals or in the special departments of the general hospitals—two subjects each afternoon. On the four Saturday forenoons Tuberculosis and Infectious Fevers are demonstrated at Ruchill Fever Hospital. Arrangements have also been made whereby a limited number of graduates may become attached to wards or out-patient departments nominally as clinical assistants for definite periods throughout the year. As such they work under the direct supervision of the physician or surgeon in charge, and carry out such detailed investigations as directed. Further information may be obtained from the Secretary of the Association, 9, Woodside-terrace, Glasgow.

The great majority of the students take their hospital course at the Western, Royal, and Victoria Infirmaries, and at the district hospitals of Glasgow Parish Council, where clinical instruction is given by professors of the University and others. Clinical instruction on Fevers is given at Ruchill and Belvidere Hospitals, while special courses, largely of a practical nature and embracing work in Hospital or Asylum wards, are conducted by University Lecturers on the Ear, the Throat and Nose, Dermatology, Ophthalmology, Venereal Diseases, Tuberculosis, Insanity, and Electro-diagnosis and Therapeutics.

ROYAL INFIRMARY, Glasgow.—The ancient connexion between the University of Glasgow and the Royal Infirmary was revived in 1911, when four University Chairs and several University Lectureships were established at the Infirmary. New Lectureships in Materia Medica and Pathological Biochemistry were established recently, and this year a lectureship in Bacteriology has been founded. St. Mungo's College which embraces and continues the original Royal Infirmary Medical School, is situated in the infirmary grounds. The infirmary has, including the Ophthalmic Department, over 800 beds. There are special wards for diseases of women, of the throat, nose, and ear, skin, eye, burns, septic cases, and biochemical investigation. The wards are open to Women Students. In addition to the large medical and surgical departments, there are departments for special diseases— viz., diseases of women, of the throat and nose, of the ear, of the eye, of the skin, and of the teeth. Five house physicians and ten house surgeons, who board in the hospital free of charge, are appointed every six months; also five non-resident house physicians, eight non-resident house surgeons, and one non-resident dental house surgeon. Clerks and dresses are appointed by the physicians and surgeons. As a large number of cases of acute diseases and accidents of a varied character are received, these appointments are very valuable and desirable. There is a modern and fully equipped Electrical Pavilion and Massage Department, and year by year the latest and most approved apparatus for diagnosis and treatment has been added. Post-graduate Classes are held during August and September in Clinical Medicine, Clinical Surgery, Clinical Gynæcology, Diseases of the Skin, Biochemistry, Diseases of the Throat, Nose and Ear, and in Diseases of the Eye. Tutorial Classes for senior students are also held in August and September.

For information regarding fees and other particulars, application should be made to the Superintendent.

GLASGOW WESTERN INFIRMARY.—This hospital of 600 beds adjoins the University. Special wards are set apart for Diseases of Women, Throat, Nose, and Ear, and for Affections of the Skin. In the out-patient department there are special clinics for Diseases of Women and for Diseases of the Throat, Ear, Teeth, Skin, Venereal Disease, and Electrotherapeutics. The Clinical Courses are given by the physicians and surgeons, each of whom conducts a separate class, and students require to enter their names at the beginning of the session for the class which they propose to attend. Special instruction is given to junior students by tutors or assistants, and clinical clerks and dressers are selected from the members of the class. All the courses of clinical instruction are recognised by the University of Glasgow and the other boards in the kingdom. In the Pathological and Bacteriological Departments the courses are both systematic and practical, and extend through the winter and following summer; these are likewise recognised by the University for graduation. In addition Post-graduate Courses are held. Eighteen resident assistants are appointed annually, without salary, from those who have completed their course. In the Clinical Laboratory students receive laboratory instruction from the lecturer on clinical methods. A School of Massage, Medical Electricity, and Swedish Remedial Exercises has been established to qualify for the Certificate of the Chartered Society of Massage and Medical Gymnastics. Secretary: J. Matheson Johnston, C.A., 87, Union-street.

VICTORIA INFIRMARY, 67, Carlton-place, Glasgow.—This institution, which has 380 beds, is the third of the extensive general hospitals in Glasgow to afford opportunity for clinical instruction to students. In addition to a full general staff there is a clinical research laboratory with pathologists and bacteriologists attached, radiological and dental instructors, and a full assortment of specialists. The Bellahouston Dispensary, also with a clinical staff, is conducted in connexion with the Victoria Infirmary. For further particulars of the clinical practice application should be made to the Secretary and Treasurer, Mr. John W. Robson.

THE ANDERSON COLLEGE OF MEDICINE, Dumbarton-road, Glasgow, W.1.—Courses are given which qualify for all the licensing boards and for the Universities of Oxford, Cambridge, London, Durham, Edinburgh, and Glasgow (the latter two under certain conditions). Extensive accommodation is provided for Practical Anatomy, Practical Chemistry, Practical Botany, Practical Zoology, Practical Physiology, Practical Pharmacy, Operative Surgery, and Public Health. Ample provision has also been made for the comfort of students. Women students are admitted on the same terms as men, and the Carnegie Trust extends its benefactions to students of the College. (Full particulars may be obtained from the Carnegie Trust Offices, Merchants' Hall, Edinburgh.)

Candidates for the L.D.S. can obtain the full medical curriculum in Anatomy, Chemistry, Physiology, Surgery, Practice of Medicine, and Materia Medica. The courses special to Dentistry are conducted at the Dental Hospital, Glasgow.

Communications relating to the College to be addressed to the Secretary of the Medical Faculty. Communications relating to the Preliminary Examination in General Education to be addressed to the Educational Institute Office, 47, Moray-place, Edinburgh; and relating to the Triple Qualification and to the Dental Qualification to be addressed to Royal Faculty Hall, 242, St. Vincent-street, Glasgow.

QUEEN MARGARET COLLEGE (Women's Department of the University).—This is an integral part of the University of Glasgow. The classes are taught by professors of the University and other lecturers appointed by the University Court, and it is governed by the University Court and Senate. The curricula, regulations, and fees are the same as those of the male students, and the University degrees are open to women on the same conditions as to men. The school of medicine is a special feature of the College, and gives full preparation for the medical degrees of the University. The women students attend classes in the various University Buildings at Gilmorehill and Queen Margaret College, the Royal Infirmary, the Western Infirmary, and the Victoria Infirmary. Facilities for clinical work are given in the Royal, Western and Victoria Infirmaries, in the Maternity, Royal Sick Children's, and other hospitals. The Arthur Scholarship is open every third year to students of first year; other Bursaries are open in Arts and Medicine, and women are admitted to certain University bursaries and fellowships.

ST. MUNGO'S COLLEGE AND GLASGOW ROYAL INFIRMARY.—The classes in St. Mungo's College qualify for the medical qualifications of the English, Scotch, and Irish Conjoint Boards, for the dental diplomas of the English, Irish, and Scottish Boards and, under certain conditions, for the various universities, including the University of London. Students who have fulfilled the conditions of the Carnegie Trust are eligible for the benefits of this Trust during the whole course of their studies at St. Mungo's College.

Further particulars can be obtained from a syllabus which may be procured free on application to the Secretary of the Medical Faculty, 86, Castle-street, Glasgow.

ROYAL HOSPITAL FOR SICK CHILDREN, St. Vincent-street, Glasgow.—This institution consists of: (1) a hospital at Yorkhill containing 275 cots, built on an elevated and central site close to the University, and opened in July, 1914; (2) a Dispensary, or Out-patient Department, in West Graham-street, opened in October, 1888; and (3) a country branch at Drumchapel, Dumbartonshire, containing 30 cots, opened in 1903. Children treated must not be over 13 years of age, nor suffer from infectious diseases. In 1927 there were 7143 patients treated in the wards, and the number of attendances of out-patients was 83,591. There are one professorship and three lectureships in the University of Glasgow in connexion with the hospital, one professorship and one lectureship on the Medical Diseases of Infancy and Childhood, one lectureship on Surgery and Orthopædics in Relation to Infancy and Childhood, and one lectureship on Bio-chemistry in relation to Infancy and Childhood. The lectures are both systematic and clinical, but particularly and chiefly the latter. In addition special facilities are given for post-graduate study.

Full information may be obtained from the Medical Superintendent.

GLASGOW ROYAL MATERNITY AND WOMEN'S HOSPITAL, Rottenrow.—114 beds. A Maternity and Child Welfare Centre has been established consisting of a complete In-door and Out-door Antenatal Department and an Infant Consultation Clinic. A new research laboratory is now open. Full particulars as to fees and accommodation may be obtained from the House Superintendent at the hospital.

ROYAL SAMARITAN HOSPITAL FOR WOMEN, Glasgow. Increased to 160 beds by building extensions completed in 1927. It offers excellent facilities for clinical instruction in the diseases peculiar to women. Lectures and clinical demonstrations are given by members of the surgical staff to students and to post-graduates; and the hospital is represented on the Board of the Glasgow Post-Graduate Medical Association formed for coördinating post-graduate medical teaching in all the hospitals. The Royal Samaritan Lectureship in Gynæcology is a University Lectureship associated with the Hospital.

For further information, application may be made at the Hospital, or to the Secretary, 149, St. Vincent-street, Glasgow.

GLASGOW LOCK HOSPITAL, 41, Rottenrow, Glasgow. Contains 80 beds for the treatment of females suffering from Venereal Diseases. There is also a Labour Ward, and a well-equipped Dispensary for out-patient attendances. There is a Lecture Room and a Laboratory, equipped with modern appliances, where University classes on the subject are dealt with. Post-graduate classes are also held. Recently the hospital has been completely renovated and modernised. Full information from the Secretary and Treasurer, Mr. J. Neilson Gray, LL.B., 65, Bath-street, Glasgow.

GLASGOW OPHTHALMIC INSTITUTION, 126, West Regent-street, and 131, Wellington-street (30 beds and six cots).—This institution is administered by the Royal Infirmary. Clinical and systematic courses of lectures for students during the winter and summer sessions. Operations on Wednesdays and Fridays. Post-graduate classes and demonstrations are arranged during the summer. Secretary and Cashier: R. Morrison Smith, C.A., 135, Buchanan-street, Glasgow.

GLASGOW EYE INFIRMARY, Berkeley-street and Charlotte-street.—The wards and dispensary are recognised by the University of Glasgow for the purpose of instruction in ophthalmology for graduation in medicine, and by the Royal Colleges of Physicians and Surgeons of England for the Diploma in Ophthalmic Medicine and Surgery. A Venereal Centre has been established, and a Branch Dispensary has been opened in Clydebank. Post-graduate Classes are held. Secretary and Acting Treasurer, Mr. Harold John Black, 171, West Regent-street, Glasgow.

GLASGOW EAR, NOSE, AND THROAT HOSPITAL, 306, St. Vincent-street (52 beds).—At out-patient and in-door departments clinical instruction is given. Post-graduate Courses are held during the year. Secretary: D. N. Mackay, 144, St. Vincent-street, Glasgow.

UNIVERSITY OF ST. ANDREWS (UNITED COLLEGE ST. ANDREWS AND UNIVERSITY COLLEGE, DUNDEE).

Four Degrees in Medicine and Surgery are conferred by the University of St. Andrews—viz., *M.B.*, *Ch.B.*, *M.D.*, *Ch.M.*, a Diploma in Public Health, and Diploma in Dental Surgery (*L.D.S.*).

The extent and standard of the Preliminary Examination is determined by the Scottish Universities Entrance Board constituted under Ordinance No. 70 of the Scottish University Courts (General No. 3—Regulations as to Admission to the Scottish Universities for purposes of graduation), in accordance with the terms of that Ordinance. A degree in Arts or in Science in any of the Universities of the United Kingdom and in some colonial and foreign universities exempts. The Preliminary Examination for graduation in Medicine and Surgery, Arts or Science, of the University of St. Andrews is accepted as equivalent to the Registration Examination required by the General Medical Council (the certificate to include the required subjects). Also the Final Examination for a degree in Arts or Science.

Degrees of Bachelor of Medicine and Bachelor of Surgery.—A pre-registration examination is held in Physics and Chemistry. Candidates must have been engaged in medical study for at least five years after registering as a medical student. In each of the first four years the candidate must have attended at least two courses of instruction in one or more of the subjects of study specified below, each course extending over a session of not less than five months, either continuous or divided into two terms, or, alternatively, one such course along with two courses, each extending over a session of not less than two and a half months. During the fifth or final year the candidate shall be engaged in clinical study for at least nine months at the Infirmary of Dundee or at one or more of such public hospitals or dispensaries, British or foreign, as may be recognised for the purpose by the University Court. The candidate must have received instruction in each of the following subjects of study, including such examinations as may be prescribed in the various classes—viz., Anatomy, Practical Anatomy, Chemistry, Materia Medica, Physiology, or Institutes of Medicine, Practice of Medicine, Surgery, Midwifery and the Diseases peculiar to Women and Infants, Pathology, Bacteriology, Practical Chemistry, Physics, Elementary Botany, Elementary Zoology, Practical Physiology, Practical Pathology, Forensic Medicine, and Public Health. The candidate must have attended for at least three years the Medical and Surgical Practice either of the Infirmary of Dundee or of a General Hospital elsewhere with not fewer than 80 patients, with a distinct staff of physicians and surgeons, and recognised for the purpose by the University Court. Additional subjects of study are Practical Pharmacy, Mental Diseases, Practical Midwifery, Operative Surgery, Vaccination, Children's Diseases, Fevers, Ophthalmology, Diseases of the Ear, Throat, and Nose, Anæsthetics, Dermatology, and Post-mortem Examinations.

With respect to the places and institutions at which the studies of the candidate may be prosecuted the following regulations shall have effect:—1. Two of the five years of medical study must be spent in the University of St. Andrews. 2. The remaining three years may be spent in any University of the United Kingdom or in any Indian, Colonial, or Foreign University recognised for the purpose by the University Court, or in such medical schools or under such teachers as may be recognised for the purpose by the University Court. Women are admitted to graduation in Medicine, subject to certain provisions.

Professional Examinations for the Degrees of Bachelor of Medicine and Bachelor of Surgery.—Each candidate will be examined both in writing and orally, and also clinically where the nature of the subject admits, in the following divisions—viz., first, in Botany, Zoology, Physics, and Chemistry; second, in Anatomy and Physiology; third, in Materia Medica, Pathology and Bacteriology, Forensic Medicine and Public Health; and fourth, in Surgery, Clinical and Operative Surgery, Practice of Medicine and Clinical Medicine, and Midwifery and Gynæcology (Systematic and Clinical).

UNIVERSITY COLLEGE, DUNDEE.—The Medical School in St. Andrews University is carried on as follows: In the case of St. Andrews tuition is given only for the first two years, up to and including Physiology and Anatomy. There are no facilities in St. Andrews for clinical studies, but a complete course is given in Dundee from the beginning to the end of the curriculum. Thus it is possible for a student to take his first two years of the curriculum in St. Andrews, transfer to Dundee and complete his course there, or take all his course in Dundee. In either case, the entire curriculum is still in the University. As regards "conjoint medical school," this term seems to refer to the point that in the United College, Dundee, which originally was not an integral part of the University, there was provision made for teaching the first two years of the medical curriculum. Subsequently, Dundee College was affiliated and these original Dundee chairs were included, but the administration of the funds is still retained by the Governors of the United College, Dundee. The remaining chairs in Dundee are financed by the University of St. Andrews. Both the Dundee professors and the St. Andrews professors in Dundee teach in a common building.

ROYAL INFIRMARY, Dundee (461 beds).—In addition to the ordinary Medical and Surgical Wards, there are special departments for Midwifery (In- and Out-door), for Diseases of Women, of Children, of the Eye, of the Ear, Nose, and Throat, and of the Skin; and for Clinical Pathology, Radiology, Electrotherapeusis, and Electrocardiography. An extension providing for a new X Ray Department and Massage Department and for additional Operation Theatre accommodation has been opened recently, a new Maternity Department is being built at a cost of £32,000, and a new Dispensary at a cost of £25,000. Clinical teaching is given to male and female students by the Honorary Staff; post-mortem examinations are conducted by [illegible] courses of instruction are [illegible] versity of St. Andrews and t[illegible] and Boards of the United Kingdom. Ten Resident Medical Officers are appointed every six months. Clinical clerks and dressers are attached to the Physicians and Surgeons; and Students are appointed as assistants in the pathological department. Further information may be obtained from the Medical Superintendent.

UNIVERSITY OF ABERDEEN.

The University of Aberdeen grants four degrees in Medicine and Surgery—viz., *M.D.*, *Ch.M.*, *M.B.*, and *Ch.B.* The Degree of Doctor of Philosophy (*Ph.D.*) is also granted in the Faculty of Medicine.

Degrees of M.B. and Ch.B.—Candidates, before entering on the curriculum, must have passed the Preliminary Examination or hold a qualification recognised as exempting from such examination, have attained the age of 17, and have passed the Pre-registration Examination in Physics and Chemistry.

The curriculum for the degrees extends over a period of five years, during which attendance is required in the following subjects: Botany, Zoology, Physics, Chemistry (Systematic and Practical), Anatomy (Systematic and Practical), Physiology (Systematic and Practical), Materia Medica and Therapeutics, Practical Pharmacy, Pathology (Systematic and Practical), Medical Jurisprudence, Public Health, Surgery, Medicine, and Midwifery.

Candidates must attend for at least three years the medical and surgical practice of a recognised hospital; they must have attended courses of at least nine months in clinical medicine and clinical surgery, and have acted as clerk in the medical and dresser in the surgical wards of a hospital. Attendance is required on the practice of a dispensary or the out-practice of a hospital and also on courses in Mental Diseases, Fevers, Ophthalmology, Post-mortem Examinations, Venereal Diseases, Tuberculosis, Radiology, X Ray, Therapeutics and Electrical Treatment, and Clinical Chemistry, and other special subjects. The candidate is also required to have been properly instructed in Vaccination and to have attended at least 20 Midwifery cases.

Degrees of M.D. and Ch.M.—Candidates for either of these degrees must already hold the degrees of M.B. and Ch.B. of Aberdeen. A thesis (in duplicate) has to be presented and an examination has to be passed in Clinical Medicine (or in some special Department of Medical Science) or Clinical Surgery, as the case may be.

Degree of Ph.D.—For this degree candidates must pursue a course of special study or research during a period of nine academical terms as Research Students in the University of Aberdeen or in any College or Institution that may be affiliated thereto. A Thesis (in duplicate) must be presented for approval.

A diploma in Public Health is granted by the University to graduates in Medicine of a University in the United Kingdom, after a special examination.

Scholarships and Prizes.—In the Faculty of Medicine of the University of Aberdeen there are the following Bursaries, Scholarships, and Prizes:—Bursaries: about 15 Bursaries (competition and presentation) are open each year, of £15 to £30 per annum in value, most of them being tenable for three years. Scholarships: five Post-graduate Scholarships, value £36 to £160 per annum. Prizes and Medals: 15 Gold Medals and Prizes for proficiency in special departments.

ABERDEEN ROYAL INFIRMARY (366 beds).—The main clinical work of the students is done in the Infirmary with its general and special facilities, including a Department of Clinical Chemistry.

ABERDEEN ROYAL MENTAL HOSPITAL.—This hospital contains, with hospital attached to main institution and agricultural branch, about 950 beds. Clinical instruction is given to students during three *months in summer. Physician-Superintendent*, Dr. R. Dods Brown.

OTHER HOSPITALS.—Students have the opportunity *of attending the following institutions: City* Fever Hospital, Sick Children's Hospital, General Dispensary, Lying-in and Vaccine Institutions, and Ophthalmic Institution.

SCOTTISH MEDICAL CORPORATIONS GRANTING DIPLOMAS.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, ROYAL COLLEGE OF SURGEONS OF EDINBURGH, ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.

These Colleges have made arrangements by which, after one series of examinations, held in Edinburgh or Glasgow, or both, the student may obtain the diplomas of the three bodies. This is the Scottish Conjoint Board.

The three bodies grant their Single Licences only to candidates who already possess legal qualifications in Medicine or Surgery.

The hospitals which are recognised by the Scottish Conjoint Board as places where professional study for their diplomas can be pursued are all those institutions which feed the medical faculties of the universities, as well as all the places which are recognised by the English and Irish Conjoint Boards.

Professional Education.—The candidate must produce certificates or other satisfactory evidence of having attended the following separate and distinct courses of instruction: Physics, three months; Elementary Biology, three months; Chemistry, six months; Practical or Analytical Chemistry, three months; Anatomy, during at least six months; Practical Anatomy, twelve months; Physiology, six months; Practical Physiology, three months; Materia Medica, three months; Pathology (including Practical Pathology), nine months; Practice of Medicine, six months; Clinical Medicine, nine months; Principles and Practice of Surgery, six months; Clinical Surgery, nine months; Midwifery, three months; Gynæcology, one course of not less than 13 meetings; Diseases of Children, one course of not less than 13 meetings; Medical Jurisprudence and Public Health, three months. The certified attendance on lectures, demonstrations, and practical work must not be less than three-fourths of the total number of roll-calls. Every student undergoes a course of Practical Midwifery, but before attending at labours he is required to attend a course of lectures on Surgery and Midwifery and to hold the offices of Clinical Medical Clerk and Surgical Dresser. He must also attend for two and a half months' instruction in Practical Pharmacy; the certificate to be signed by the teacher, who must be a member of the Pharmaceutical Society of Great Britain, or the superintendent of the laboratory of a public hospital or dispensary, or a registered practitioner who dispenses medicines to his patients, or a teacher of Practical Pharmacy.

The student must attend for 27 months the Medical and Surgical practice of a public general hospital containing on an average at least 80 patients available for clinical instruction, and possessing distinct staffs of physicians and of surgeons. He must act as Surgical Dresser and Medical Clinical Clerk for not less than six months in the wards in each case, and receive practical instruction in administration of anæsthetics. He must attend for six months the practice of a public dispensary especially recognised by any of the above authorities, or the out-patient practice of a recognised general hospital. This attendance should be made after the student has passed the First and Second examinations.

Candidates are also required to attend the following courses: Diseases and Injuries of the Eye, three months; Insanity, three months; Infectious Diseases, three months; Gynæcology, three months; Diseases of Children, three months.

The curriculum lasts for five years, the fifth year being devoted to clinical work.

There are four professional examinations:—

First Examination includes Physics, Chemistry, and Elementary Biology.

Second Examination includes Anatomy and Physiology and Histology; and candidates may be admitted to this examination at the end of the second year of medical study.

Third Examination includes Pathology and Materia Medica with Pharmacology.

Final Examination.—The Final Examination shall not be taken earlier than the end of the fifth year of study and shall embrace the following subjects:—Medicine, including Therapeutics, Medical Anatomy, and Clinical Medicine; Surgery, including Surgical Anatomy, Clinical Surgery, and Diseases and Injuries of the Eye; Midwifery and Diseases of Women; and, if not passed previously, Medical Jurisprudence and Public Health; but it is optional to candidates who have passed the Third Examination to be admitted to the subject of Medical Jurisprudence and Public Health on lodging certificates of having attended the necessary course *in that* subject at any time; but the subjects of Medicine, Surgery, and Midwifery shall be taken together at any time after the end of the fifth Winter Session, provided that a period of [illegible] *months has elapsed* since passing the Second Examination. All candidates shall be subjected, in addition to the written and oral examinations, to clinical examinations in Medicine and Surgery, which shall include the Examination of Patients, Physical Diagnosis, the Clinical Use of the Microscope, Examination of the Urine and Urinary Deposits, Surgical Appliances, Bandages, and Surface Marking.

There are four periods of examination annually.

The Registrar in Edinburgh is Mr. D. L. Eadie, 49, Lauriston-place; and the Registrar in Glasgow, Mr. Walter Hurst, 252, St. Vincent-street, to whom fees and *certificates* must be sent for the respective examinations, and from whom particulars of fees can be obtained.

For students registered with the General Medical Council after Jan. 1st, [illegible], more extensive Regulations are in force, and candidates applying for Regulations should state date of registration.

SCHOOL OF MEDICINE OF THE ROYAL COLLEGES, Edinburgh.—The number of students varies much in the classes and subjects. It is within the limit to say that about [illegible] students avail themselves each session of the opportunity of attending the school. The lectures qualify for the University of Edinburgh and other Universities, the Royal Colleges of Physicians and Surgeons of London, Edinburgh, and Dublin, the Faculty of Physicians and Surgeons of Glasgow, and other Medical and Surgical and Public Boards. Special courses of instruction for dental students are also included in the curriculum of this school. The practical classes and laboratories will open and the lectures commence on Oct. 2nd. In accordance with the statutes of the University of Edinburgh one-half of the qualifying classes required for graduation may be attended in this school. The regulations require that the fee for any class taken for graduation in Edinburgh shall be the same as that for the corresponding class in the University. The whole education required for graduation at the University of London may be taken in this school. Post-graduate Courses are conducted in conjunction with the University. Further particulars regarding the school, also its calendar (price 6*d.*) may be had on application to the Dean of the School, Edinburgh.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

In addition to the diplomas granted by the Scottish Conjoint Board the Royal College of Physicians grants its Single Licence to candidates already possessing legal qualifications for professional practice.

The Royal College of Physicians of Edinburgh grants a *Membership* and a *Fellowship.*

Membership.—A candidate, who must be a Licentiate of a British or Irish College of Physicians, or a graduate in medicine of a University, approved by the Council, and 24 years of age, is examined in medicine, therapeutics, and in any branch of the departments of medicine specially professed, such as general pathology, psychology, public health obstetrics, gynæcology, diseases of children, tropical medicine, or medical jurisprudence.

Fellowship.—The Fellows are selected from the ranks of the *Members.*

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.

The Royal College of Surgeons of Edinburgh admits to the examination for its Single Licence any candidates who hold a Diploma in Medicine of any British, Indian, or Foreign university or of any British College of Physicians, or of the Society of Apothecaries of London or Apothecaries' Hall, Dublin, granted under the provisions of the Medical Act, 1886, whose preliminary examination and course of professional study is proved to be sufficient to fulfil the requirements of the College, or to those who have passed a full examination for any of the above. Female practitioners are admitted to the Licence of the College and also to the Fellowship, and the regulations apply to practitioners of either sex.

The College grants a diploma of Fellowship after examination to the holders of British surgical degrees or diplomas and the holders of recognised degrees of the Universities of Canada, Australia, New Zealand, and the Indian Empire.

The Fellowship.—Candidates must be 25 years of age and in practice for at least two years. The examination is written and viva voce, and includes surgery and surgical anatomy, operative surgery, and clinical practice. One optional subject must also be taken, the range of these specialisms covering nearly every branch of medicine. Candidates are not allowed to appear for more than three times at the examinations. One month's notice of intention to appear for examination must be given by the candidate to the College.

THE ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.

The Royal Faculty of Physicians and Surgeons of Glasgow grants a Fellowship and a Licence to be held separately. The Licence is granted as a separate qualification to qualified practitioners in Medicine after examination in surgery, including surgical anatomy and clinical surgery.

Fellowship.—The Fellowship of the Faculty is granted after examination in medicine or surgery, together with an optional subject, which may be anatomy or physiology or be selected from any special branch of medicine or surgery. Fourteen days' notice must be given by the candidate to the Faculty. In certain circumstances Fellows may be elected as a mark of distinction.

III.—IRELAND.

THE UNIVERSITIES.

UNIVERSITY OF DUBLIN, TRINITY COLLEGE (SCHOOL OF PHYSIC).

Matriculation.—University students take the Entrance of Trinity College and a Junior Freshman Term or a special Medical Preliminary; Extern Students, any examination recognised by the General Medical Council.

Pre-registration Examination in Elementary Physics and Chemistry.—Before beginning the five years' Medical curriculum students must pass an examination in elementary Physics and Chemistry. This examination is held at the end of September, in January, in March, and in June. Courses in preparation for it may be taken in the School of Physic.

Degrees in Medicine (M.B.), Surgery (B.Ch.), and Midwifery (B.A.O.).—Candidates for these degrees must be of B.A. standing and must be for at least five academic years on the books of the Medical School, reckoned from the date of registration. The Arts course may be taken concurrently with the Medical course, and the B.A. degree need not be taken before the final medical examinations, but the Medical degrees are not conferred without the Arts degree. The following courses must be attended:—(1) Lectures—Botany, Zoology, Physics and Practical Physics; Systematic, Descriptive and Applied Anatomy; Chemistry and Practical Chemistry; Histology, Physiology, Practical and Applied Physiology; Practice of Medicine; Midwifery and Gynæcology, Pathology and Bacteriology; Materia Medica and Therapeutics; Medical Jurisprudence and Hygiene; Surgery and Operative Surgery; (2) three courses of nine months' attendance on the Clinical Lectures of Sir Patrick Dun's or other recognised Hospital; (3) Practical Vaccination, one month's instruction; (4) Mental Disease, three months; (5) Practical Midwifery with Clinical Lectures, including not less than 20 personally conducted cases, six months; (6) Ophthalmic Surgery, three months. Three groups of examinations have to be passed. Preliminary Scientific Examination, including Physics and Chemistry, Botany, and Zoology. The Intermediate Medical, Part I., including Anatomy, Physiology, and Organic Chemistry; and Part II., including Applied Anatomy and Applied Physiology; and the Final Examination, which is divided into Part I., Materia Medica and Therapeutics. Hygiene and Jurisprudence, Pathology and Bacteriology; and Part II., Medicine, including Clinical Medicine and Mental Diseases; Surgery, including Operative and Ophthalmic Surgery; Midwifery and Gynæcology. Part I. may be passed in the fourth year, and Part II. completed at the end of the fifth.

Doctor in Medicine.—A Doctor in Medicine must have passed all the qualifying examinations and must be a B.A. of three years' standing. He must also submit a thesis and pass an Examination before the Regius Professor of Physic.

Master in Surgery.—A Master in Surgery must be a Bachelor in Surgery of the University of Dublin of not less than three years' standing, and must produce satisfactory evidence of having been engaged for not less than two years from the date of his registration in the study, or study and practice, of his profession. He must then pass a special examination.

Master in Obstetric Science.—A Master in Obstetric Science must be a Bachelor in Obstetric Science of two years' standing, and must produce evidence of having been engaged in the study of Obstetric Medicine and Surgery during two years. He is then required to pass a special examination.

Diploma in Gynæcology and Obstetrics.—A post-graduate diploma is conferred upon registered medical practitioners who take a six months' course at the Rotunda Hospital or other recognised institution, a six months' course in Trinity College, and then pass a special examination. The minimum time required for the complete course is nine months.

Bachelor in Dental Science and Master in Dental Science.—The regulations under which these degrees are awarded can be obtained by application to the Registrar of the School of Physic.

All Degrees and Courses of Instruction are open to women students.

Scholarships and Prizes.—1. Medical and Surgical Travelling Prizes, £100, awarded in alternate years. 2. Bicentenary Memorial Prize, £30, awarded yearly, and given to the Travelling Prize man. 3. Sir John Banks Prize and Medal. 4. Edward Hallaran Bennett Prize and Medal. 5. FitzPatrick Scholarship, awarded on results of Final Examination (interest on £1000). 6. Medical Scholarship, £20 per annum for two years, awarded in Chemistry, Physics, Botany, and Zoology. 7. Medical Scholarship in Anatomy and Physiology, £20 per annum for two years. 8. Henry Hutchinson Stewart Scholarships, one in Botany, Zoology, Chemistry and Physics, and another in Anatomy and Physiology, awarded annually and valued at £10 per annum for three years. 9. Henry Hutchinson Stewart Scholarship in Mental Diseases, awarded from time to time, £50 per annum for three years. 10. John Mallet Purser Medal, awarded annually in Physiology. 11. Daniel John Cunningham Medal and Prize, awarded annually in Anatomy. 12. Begley Studentship, £40 per annum for four years, awarded annually. 13. Kingsmill Jones Memorial Prize, awarded annually in Natural and Experimental Science, £15. 14. O'Sullivan Memorial Scholarship, £48 awarded annually for excellency of record in school.

Post-graduate Instruction.—Arrangements have been made, with the approval of the Board of Trinity College, for a post-graduate course of instruction at the School of Physic during the autumn from Monday, Sept. 17th, to Saturday, Oct. 6th. Members of the class can reside in college rooms and dine on commons.

HOSPITALS AFFORDING PRACTICE RECOGNISED BY THE IRISH UNIVERSITIES AND CORPORATIONS.[1]

SIR PATRICK DUN'S HOSPITAL, Grand Canal-street, Dublin.—Classes both in Medicine and Surgery are held each morning from 9 o'clock from Oct. 1st till the end of June. Special classes for junior students will be held in the wards during the months of October, November, and December. A Resident Surgeon, with salary, is appointed annually. Six Resident Pupils are appointed every six months. Twelve surgical Dressers and twelve Clinical Clerks are appointed each month. There are facilities for women students.

The practice of the hospital is open to all students, and the certificates are recognised by Dublin University, the National University and Royal Colleges of Surgeons of England, Ireland, and Scotland. It is an official "Treatment Centre" for venereal diseases.

Prizes and Medals.—Clinical medals and prizes amounting to about £21 each will be awarded in Medicine and in Surgery respectively in accordance with the will of the late Rev. Samuel Haughton, M.D., S.F.T.C.D. Candidates who fail to obtain these medals and prizes will be awarded special certificates in Medicine and in Surgery provided they show sufficient merit.

Further information will be supplied by the Hon. Secretary to the Medical Board.

ADELAIDE HOSPITAL, Peter-street, Dublin.—Two resident surgeons are elected half-yearly and four or more resident pupils every six months. At the termination of the session prizes in Clinical Medicine, in Surgery, in Gynæcology, and in Dermatology will be awarded.

Prizes.—Wallace Beatty Memorial bursaries are awarded at the commencement of the winter session. In addition to the junior prizes the Hudson Scholarship, £30 and a gold medal, as well as a prize of £10 together with a silver medal, are awarded at the end of the session for proficiency in medicine, surgery, gynæcology, and pathology.

The certificates of attendance are recognised by all the Universities and licensing bodies in the United Kingdom. Further particulars may be obtained from the Secretary of the Hospital.

MATER MISERICORDIÆ HOSPITAL, Dublin. (Under the care of the Sisters of Mercy.)—This Hospital, containing 382 beds, is open at all hours for the reception of accidents and urgent cases. Clinical instruction is given by the Physicians and Surgeons at 9 A.M. daily. Ophthalmic Surgery is taught in the Special Wards and in the Dispensary. Surgical operations are performed daily. Connected with the hospital are extensive Dispensaries, which afford valuable opportunities for the study of general Medical and Surgical Diseases, and Accidents; a fully-equipped Biochemical Laboratory, a modern Electro-Massage Department, and Electrocardiograph room. Instruction is given on Pathology and Bacteriology. Three House Physicians, eight House Surgeons, and 18 resident pupils are elected annually. Dressers and Clinical Clerks are appointed regularly and certificates given for merit. Leonard Prizes will be offered for competition annually. Certificates of attendance are recognised by all the Universities and licensing bodies in the United Kingdom. There is a Private Hospital for the reception of Medical and Surgical cases. A Training School and a Home for Trained Nurses are connected with the Hospital, and Nurses who have passed a qualifying examination can be obtained on application to the Lady Superior.

Entries can be made with any of the physicians or surgeons, or with the Registrar, 13, Merrion-square. Detailed information may be obtained from the Secretary, Medical Board.

MERCER'S HOSPITAL.—This hospital contains 120 beds for medical and surgical cases, and arrangements have been made with the medical officers of Cork-street Fever Hospital whereby all students of this hospital are entitled to attend the clinical instruction of that institution and become eligible for the resident posts. There is a large dispensary for out-patients and a modern X ray department. An electrocardiograph has been installed. Students of the hospital are permitted to attend the gynæcological department, where they receive practical instruction. There are special wards for the treatment and study of children's diseases. A gold medal is awarded annually to the best student. During the past few years the hospital has undergone extensive alterations in order to bring it up to modern requirements. A House Surgeon is appointed annually. There are six men and two women Resident Pupils, and Clinical Clerks and Dressers are appointed from members of the classes.

For further particulars apply to Dr. Leonard Abrahamson, Hon. Sec., Medical Board, 40, Fitzwilliam-place.

---

[1] This list of the institutions recognised by the Conjoint Board of Ireland is supplemented in the regulations of the Colleges by those hospitals mentioned as recognised institutions in Scotland and England. The recognised facilities for clinical instruction in some of the Irish centres have been described.

Richmond, Whitworth, and Hardwicke Hospitals (House of Industry Hospitals), Dublin.—These hospitals contain 330 beds—130 for Surgical cases, 80 for Medical cases, 78 for Fever and other Epidemic Diseases, and an Auxiliary Wing of 42 beds. A Resident Physician and a Resident Surgeon are appointed each half year and are paid for their services. Resident Clinical Clerks are appointed each quarter and provided with furnished apartments and fuel. These appointments are open not only to advanced students but also to those who are qualified in Medicine and Surgery. The Dressers are selected from among the best qualified of the pupils without the payment of any additional fee. Women students are eligible for election as residents, and special apartments are reserved for their use. Extensive alterations and improvements have recently been made in the X ray, electrotherapeutic, and electrocardiographic departments. For information apply to Dr. G. E. Nesbitt, 71, St. Stephen's Green, Dublin.

Royal City of Dublin Hospital.—158 beds and a special wing for the treatment of fevers and contagious diseases founded by the late Mr. Drummond. There is a large nursery where special opportunities are afforded for the study of diseases of children, both medical and surgical. There are also special wards for ophthalmic, aural, and gynæcological cases. There is a largely attended out-patient department, where students are allowed to attend accidents and dress cases under supervision. Six resident pupils are appointed every three months. A House Surgeon and a House Physician are appointed annually. For information apply to the Secretary.

Dr. Steevens' Hospital, Dublin (Kingsbridge).—250 beds, only 150 now in use. There is accommodation for 10 resident pupils, each of whom is provided with a separate bedroom, and board is supplied by the hospital at a reasonable rate. There is an Electric Massage Department, a " Sun-Ray " Department, and an X Ray Department. There are also two V.D. wards and a largely attended V.D. Treatment Centre. All information with regard to the terms for such residency can be had from the Resident Surgeon at the Hospital. Secretary: E. D. F. Banks.

Meath Hospital and County Dublin Infirmary.* 150 beds are available for clinical teaching. A building containing 40 of these beds intended for the isolated treatment of fevers is attached to the hospital. The certificates of this hospital are recognised by all the universities and licensing bodies of the United Kingdom. Medical Clinical Clerks and Surgical Resident Pupils and Dressers are appointed every three months. Two House Surgeons and a Resident Casualty Officer are elected twice annually. The Smyth Memorial Prize in Medicine, value £50, is awarded in alternate years and is open to students of the hospital who have attended for at least two academic years. The next examination will be held in June, 1929. The Treasurer of the Medical Board will give full information.

Jervis-street Hospital, Dublin.*—Founded 1718; rebuilt 1886. 130 beds. The operation theatre contains all modern requirements.

Rotunda Hospital, Dublin.—This institution is the largest combined gynæcological and maternity hospital in the British Empire. Over 4000 confinements are attended annually and upwards of 1000 gynæcological patients admitted. Students can take out their necessary gynæcological and midwifery practical courses. The work of the hospital is carried on continuously through the year, and consists of daily clinical instruction in the maternity department and examination and operations in the gynæcological department. Qualified students are given facilities for studying and assisting in the management of all abnormal cases so far as is practical. An antenatal dispensary is held three times weekly and all students are encouraged to attend. A special class in gynæcological examination and diagnosis is conducted by the Assistants to the Master. In addition there is a special class in operative obstetrics, limited in number. The pathological laboratory is under the supervision of a skilled pathologist, who gives special classes at intervals. There is a fully equipped X ray installation under the care of a competent radiologist. A ward has been opened for the treatment of infantile conditions, and is under the care of a pediatrician, who gives instruction in the out-patient department, which is held daily. The appointments on the staff of the hospital are given to qualified past students of the hospital who have taken the L.M. and consist of Extern Assistants for six months, one being appointed every three months. From these the Assistants to the Master are appointed. Women students can reside in the hospital on the same terms as men. The mess room and sleeping quarters have been decorated recently and reading rooms are provided. The L.M. is granted by examination after a six months' course. Fees for Intern students: one month £6 6*s.*, months other than the first £4 4*s.*, three months £12 12*s.*, six months £21. Special gynæcological class £2 2*s.* per month. For further particulars apply to the Master, Dr. Bethel Solomons, F.R.C.P.I.

Coombe Lying-in Hospital and Guinness Dispensary for the Treatment of Diseases Peculiar to Women, Dublin.—This hospital contains 70 beds and consists of two divisions, one of which is devoted to lying-in cases and the other to the treatment of diseases peculiar to women. Lectures are delivered, practical instruction given, and gynæcological operations are performed in the theatres daily. There is a general dispensary held daily, at which instruction is given on the Diseases of Women and Children. There is a special afternoon dispensary held by the Master and his assistants, at which practical instruction in gynæcology is given. There is no extra charge for attendance at this Dispensary. There is accommodation for intern pupils, who enjoy exceptional advantages of acquiring a thorough knowledge of this branch of their profession. Women students can reside in the hospital. Clinical assistants are appointed from amongst the pupils as vacancies occur. Certificates of attendance at this hospital are accepted by all licensing bodies. Students can enter for attendance at any time, but preference is given to those entering from the first day of the month. Further particulars may be had on application to the Master or the Registrar at the Hospital.

National Maternity Hospital, Holles-street, Dublin.—Established 1894. The hospital consists of Intern and Extern Maternity, Gynæcological Wards, and a Dispensary for the treatment of Diseases of Women and Children and an antenatal and postnatal branch. Every facility is given for the carrying out of practical work. Undergraduate and postgraduate courses are arranged at any time. Certificates of attendance at this hospital are recognised by all the licensing bodies. Clinical lectures are given daily and Oral lectures four times per week. The L.M. Diploma is given by special examination, which is held three times a year. Further particulars can be obtained from the Master or from the Secretary, Holles-street, Dublin.

St. Vincent's Hospital and Dispensary, Dublin.—Established 1834. 200 beds. Clinical Lectures in Medicine and Surgery are held from October to June. Special classes for Juniors from October to December. Pathological and Bacteriological Demonstrations are given every Thursday, and instructions in the use of Laryngoscope and Otoscope for senior students every Saturday. Medals and Prizes: the Bellingham gold medal in Medicine and the O'Farrell gold medal in Surgery are offered for competition at the end of the summer session, as well as junior prizes, also the

* No returns.

McArdle Memorial Prize, value £20. There are a large Extern Department and a new Pathological Laboratory. Hon. Secretary Medical Board, Wm. Doolin, M.B., F.R.C.S., 2, Fitzwilliam-square, Dublin.

NATIONAL UNIVERSITY OF IRELAND.*

Matriculation.—All students must pass a matriculation examination; the examination taking place in June and September in Dublin, and at certain local centres, includes five subjects, three of which must be Irish, English, and mathematics. All students must pass in Irish except students not born in Ireland, and other students whose home residence shall have been outside Ireland during the three years immediately preceding their matriculation; but all such students will be expected to attend a course of instruction in Irish Literature and History prior to obtaining any degree in the University. The following are the subjects for examination:—1. Irish. 2. Latin or Greek. 3. French, German, Italian, Spanish, Portuguese, Welsh, or any other modern language approved by the Senate. 4. English 5. Mathematics. 6. Latin, Greek, French, German, Welsh, Spanish, Italian, Portuguese, or any other modern language approved by the Senate, History, Geography, Applied Mathematics, or Physics as an alternative, Chemistry, Botany, Agricultural Science, Commerce, Music, and for women candidates only Physiology and Hygiene. Students entering for degrees in Medicine or Dentistry, if already registered by the General Medical Council, must take Irish, Latin, English, Mathematics, and a fifth subject.

The medical degrees granted are:—

M.B., B.Ch., and B.A.O.; and M.D., M.Ch., and M.A.O., Ph.D.—Printed forms of application for admission to any medical examination may be had from "The Registrar, The National University of Ireland, Dublin."

The Constituent Colleges of the National University of Ireland at which the full curriculum for medical degrees can be obtained are University College, Dublin; University College, Cork; and University College, Galway.

UNIVERSITY COLLEGE, DUBLIN.—*Matriculation.*—Almost all the students of the College are matriculated students of the National University of Ireland. The pre-registration examination in physics and chemistry is taken after matriculation either at the beginning of or during the winter session. The course is of five years' duration and dates from the passing of the pre-registration examination.

Degrees of M.B., B.Ch., and B.A.O.—The First Examination includes Applied Physics, Applied Chemistry, Botany, Zoology, and Applied Biology. The examination may be taken in two parts: Part I., Physics and Chemistry; Part II., Botany and Zoology. Honours may be obtained only when both parts are taken as one examination. The Second Examination includes Anatomy and Physiology. Both must be passed at the same time. The Third Examination (Part I.) includes Pathology, Materia Medica, Pharmacology, and Therapeutics. Part II. (Third Examination), taken at the end of the Fourth Winter Session, includes Hygiene and Medical Jurisprudence.

The Final Examination in Medicine, Midwifery, Surgery, and Ophthalmology includes both the theoretical and the clinical branches. No student can enter for the M.B., B.Ch., or B.A.O. until the end of the fifth year after registration, when the curriculum has been completed. The degree of M.D. may be obtained either by examination or on published work.

A Post-graduate Summer Course is held each year, beginning about the middle of June. The D.P.H. Course extends over the year, beginning at the opening of the session.

UNIVERSITY COLLEGE, CORK: THE SCHOOL OF MEDICINE.—Students must have passed the Matriculation Examination of the University or some other recognised examination, and a preliminary examination recognised by the General Medical Council.

Medical Students who have passed the First Professional Examination of the Conjoint Boards of Ireland, England, or Scotland may be admitted to the rank of second-year students on making application to the Council. Similarly, students who have passed the Second Professional Examination of the same Boards may be admitted to the rank of third-year students; and those who have passed the Third Professional Examination of the Dublin Colleges, or of the Edinburgh Colleges and Glasgow Faculties, may rank as fourth-year.

The school is provided with physiological, toxicological, pathological, and pharmaceutical laboratories, materia medica, anatomical and pathological museums, as well as a collection of surgical and obstetrical instruments and appliances. There are dissecting-rooms, well-appointed physical, chemical, and biological laboratories, a large natural history museum in the adjoining building, and part of the College ground is laid out as a botanical garden. The plant houses are well filled with plants and are open to the students in the class of Botany. The Library contains about 70,000 volumes and is open daily during term time to students. The Medical Museum occupies a large room erected at the northern end of the medical buildings. There are Students' Clubs for men and women students of the College and various athletic clubs.

Residence of Students.—Students not living at home, or with relatives or friends, sanctioned by their parents or guardians, are required to live in a hostel or in recognised lodgings, and register their addresses each session. The Honan Hostel, adjoining the College, is equipped by private endowment. A number of sets of rooms, together with recreation and common rooms, are provided for lay students who may desire to live there. For full particulars apply to the Warden. The Ursuline Convent, Blackrock, has a house of residence, quite separate from their Secondary School, for Catholic women students.

Clinical Instruction.—Students may attend the South Charitable Infirmary and County of Cork General Hospital, Cork North Charitable Infirmary and City of Cork General Hospital, the Mercy Hospital, the Cork District Lunatic Asylum, the Victoria Hospital for Diseases of Women and Children, the County Lying-in Hospital, Bon Secours, Fever, the District, and Ear, Eye, and Throat Hospitals.

Complete information with regard to class fees, scholarships, and prizes can be obtained from the Dean of the Medical Faculty, and in respect of the hospitals from the Secretaries.

UNIVERSITY COLLEGE, GALWAY: SCHOOL OF MEDICINE.—The College contains a well-lighted and ventilated dissecting-room and an anatomical lecture theatre; physiological, pathological, pharmaceutical, chemical, and physical laboratories; anatomical, pathological, gynæcological, and materia medica museums; as well as large natural history and geological museums and an extensive library in which students can read and from which they can borrow books. There are 12 Entrance Scholarships, value £25 each, for which Medical Students compete with other students on the Entrance Course. In the Second, Third, and Fourth years three Scholarships in each year, value £25 each, are reserved for Medical Students. H. H. Stewart Scholarships (£10 a year for three years) are awarded by the University in Anatomy and Physiology at Second Medical Examination amongst Students of the three constituent Colleges. Travelling Studentships (£200 a year for two years) are offered by the University for competition amongst Medical Graduates of the three Colleges of not more than two years' standing. Women students are eligible for all College and University Degrees, Distinctions, and Prizes. There are extensive grounds, a portion of which

RICHMOND, WHITWORTH, AND HARDWICKE HOSPITALS (HOUSE OF INDUSTRY HOSPITALS), Dublin.—These hospitals contain 330 beds—130 for Surgical cases, 80 for Medical cases, 78 for Fever and other Epidemic Diseases, and an Auxiliary Wing of 42 beds. A Resident Physician and a Resident Surgeon are appointed each half year and are paid for their services. Resident Clinical Clerks are appointed each quarter and provided with furnished apartments and fuel. These appointments are open not only to advanced students but also to those who are qualified in Medicine and Surgery. The Dressers are selected from among the best qualified of the pupils without the payment of any additional fee. Women students are eligible for election as residents, and special apartments are reserved for their use. Extensive alterations and improvements have recently been made in the X ray, electrotherapeutic, and electrocardiographic departments. For information apply to Dr. G. E. Nesbitt, 71, St. Stephen's Green, Dublin.

ROYAL CITY OF DUBLIN HOSPITAL.—158 beds and a special wing for the treatment of fevers and contagious diseases founded by the late Mr. Drummond. There is a large nursery where special opportunities are afforded for the study of diseases of children, both medical and surgical. There are also special wards for ophthalmic, aural, and gynæcological cases. There is a largely attended out-patient department, where students are allowed to attend accidents and dress cases under supervision. Six resident pupils are appointed every three months. A House Surgeon and a House Physician are appointed annually. For information apply to the Secretary.

DR. STEEVENS' HOSPITAL, Dublin (Kingsbridge).—250 beds, only 150 now in use. There is accommodation for 10 resident pupils, each of whom is provided with a separate bedroom, and board is supplied by the hospital at a reasonable rate. There is an Electric Massage Department, a " Sun-Ray " Department, and an X Ray Department. There are also two V.D. wards and a largely attended V.D. Treatment Centre. All information with regard to the terms for such residency can be had from the Resident Surgeon at the Hospital. Secretary: E. D. F. Banks.

MEATH HOSPITAL AND COUNTY DUBLIN INFIRMARY.* 150 beds are available for clinical teaching. A building containing 40 of these beds intended for the isolated treatment of fevers is attached to the hospital. The certificates of this hospital are recognised by all the universities and licensing bodies of the United Kingdom. Medical Clinical Clerks and Surgical Resident Pupils and Dressers are appointed every three months. Two House Surgeons and a Resident Casualty Officer are elected twice annually. The Smyth Memorial Prize in Medicine, value £50, is awarded in alternate years and is open to students of the hospital who have attended for at least two academic years. The next examination will be held in June, 1929. The Treasurer of the Medical Board will give full information.

JERVIS-STREET HOSPITAL, Dublin.*—Founded 1718; rebuilt 1886. 130 beds. The operation theatre contains all modern requirements.

ROTUNDA HOSPITAL, Dublin.—This institution is the largest combined gynæcological and maternity hospital in the British Empire. Over 4000 confinements are attended annually and upwards of 1000 gynæcological patients admitted. Students can take out their necessary gynæcological and midwifery practical courses. The work of the hospital is carried on continuously through the year, and consists of daily clinical instruction in the maternity department and examination and operations in the gynæcological department. Qualified students are given facilities for studying and assisting in the management of all abnormal cases so far as is practical. An *antenatal* dispensary is held three times weekly and all students are encouraged to attend. A special class in gynæcological examination and diagnosis is conducted by the Assistants to the Master. In addition there is a special class in operative obstetrics, limited in number. The pathological laboratory is under the supervision of a skilled pathologist, who gives special classes at intervals. There is a fully equipped X ray installation under the care of a competent radiologist. A ward has been opened for the treatment of infantile conditions, and is under the care of a pediatrician, who gives instruction in the out-patient department, which is held daily. The appointments on the staff of the hospital are given to qualified past students of the hospital who have taken the L.M. and consist of Extern Assistants for six months, one being appointed every three months. From these the Assistants to the Master are appointed. Women students can reside in the hospital on the same terms as men. The mess room and sleeping quarters have been decorated recently and reading rooms are provided. The L.M. is granted by examination after a six months' course. Fees for Intern students: one month £6 6*s*., months other than the first £4 4*s*., three months £12 12*s*., six months £21. Special gynæcological class £2 2*s*. per month. For further particulars apply to the Master, Dr. Bethel Solomons, F.R.C.P.I.

COOMBE LYING-IN HOSPITAL AND GUINNESS DISPENSARY FOR THE TREATMENT OF DISEASES PECULIAR TO WOMEN, Dublin.—This hospital contains 70 beds and consists of two divisions, one of which is devoted to lying-in cases and the other to the treatment of diseases peculiar to women. Lectures are delivered, practical instruction given, and gynæcological operations are performed in the theatres daily. There is a general dispensary held daily, at which instruction is given on the Diseases of Women and Children. There is a special afternoon dispensary held by the Master and his assistants, at which practical instruction in gynæcology is given. There is no extra charge for attendance at this Dispensary. There is accommodation for intern pupils, who enjoy exceptional advantages of acquiring a thorough knowledge of this branch of their profession. Women students can reside in the hospital. Clinical assistants are appointed from amongst the pupils as vacancies occur. Certificates of attendance at this hospital are accepted by all licensing bodies. Students can enter for attendance at any time, but preference is given to those entering from the first day of the month. Further particulars may be had on application to the Master or the Registrar at the Hospital.

NATIONAL MATERNITY HOSPITAL, Holles-street, Dublin.—Established 1894. The hospital consists of Intern and Extern Maternity, Gynæcological Wards, and a Dispensary for the treatment of Diseases of Women and Children and an antenatal and post-natal branch. Every facility is given for the carrying out of practical work. Undergraduate and post-graduate courses are arranged at any time. Certificates of attendance at this hospital are recognised by all the licensing bodies. Clinical lectures are given daily and Oral lectures four times per week. The L.M. Diploma is given by special examination, which is held three times a year. Further particulars can be obtained from the Master or from the Secretary, Holles-street, Dublin.

ST. VINCENT'S HOSPITAL AND DISPENSARY, Dublin.—Established 1834. 200 beds. Clinical Lectures in Medicine and Surgery are held from October to June. Special classes for Juniors from October to December. Pathological and Bacteriological Demonstrations are given every Thursday, and instructions in the use of Laryngoscope and Otoscope for senior students every Saturday. Medals and Prizes: the Bellingham gold medal in Medicine and the O'Farrell gold medal in Surgery are offered for competition at the end of the summer session, as well as junior prizes, also the for the work of practically instructing students in the compounding and dispensing of medicines.

---

* No returns.

Clinical Instruction.—The following institutions are recognised by the University as affording proper opportunities for clinical instruction: the Royal Victoria Hospital, the Mater Infirmorum Hospital, the Union Hospitals, the Belfast Hospital for Sick Children, the Belfast Maternity, the Ulster Hospital for Women and Children, the Ulster Eye, Ear, and Throat Hospital, the Belfast Ophthalmic Hospital, the Purdysburn Fever Hospital, and the Belfast District Lunatic Asylum. Complete information can be obtained from the respective Secretaries.

Royal Victoria Hospital, Belfast, 436 beds.—Students eligible for McGrath, McQuitty, Malcolm, Coulter Smyth and Elwood Scholarships aggregate annual value £185. Twelve House Surgeons and House Physicians. Thirty-six resident pupilships, three months each, annually for Senior Students, of which a proportion is allotted to Women Students, Special Departments for Radiology, Clinical Pathology, V.D., Dermatology, Gynæcology, Vaccine Therapy, Electrocardiography, Dentistry.

Mater Infirmorum Hospital, Belfast.—This hospital contains 270 beds and is open at all hours for the reception of accidents and urgent cases. Clinical instruction is given daily by Physicians and Surgeons. Surgical operations are performed daily. The outpatient departments in Medicine and Surgery, also the special dispensaries for Gynæcology, Ear, Eye and Throat, Electrotherapeutics, Venereal Diseases are very largely attended and afford valuable opportunities to students for the study of those subjects. A House Physician and two House Surgeons are elected every six months. Resident pupils are admitted as the vacancies arise. Three Exhibitions and a Gold Medal are competed for annually in June. Certificates of attendance upon this hospital are recognised by all the Universities and licensing bodies in the United Kingdom.

Belfast Infirmary and Hospital (1600 beds).—Clinical courses are given quarterly, and a course for D.P.H. in Hospital. Intern Venereal Clinic in Infirmary under Corporation scheme. Maternity Hospital recognised for Practical Midwifery training. Particulars may be obtained on application to the Hon. Sec. Visiting Medical Staff. Certificate of vaccination class recognised by Local Government Board. There is a department for Cancer with 32 beds, and X Ray and Bacteriological Departments.

The Belfast Hospital for Sick Children, Queen-street (45 beds).—Clinical instruction is given in this hospital. During the Winter Session two Courses of Lectures are delivered on the Medical and Surgical Diseases incidental to Infancy and Childhood. Demonstrations in Ophthalmology and Pathology are given, and ample opportunities are afforded in the wards and in the Out-patient Department for gaining a practical and theoretical knowledge of the diseases of Infancy and Childhood. This Hospital grants Certificates in Diseases of Children, which are recognised by the various Examining Bodies. Certificates are also granted for post-graduate study. A Gold Medal is offered for competition at the close of the session.

Maternity Hospital, Townsend-street, Belfast.—Twenty-five beds in constant occupation, and exclusively devoted to Midwifery and Antenatal conditions. There is also a large district. The Queen's University of Belfast have erected a Students' Hostel in connexion with the Hospital where six Students and Post-graduates are received each month. The University Tutor in Obstetrics resides in the Hostel and Students conduct their cases under his supervision. There is a large Antenatal Department and a Department for Venereal Diseases. Communications should be made to C. H. G. Macafee, M.B., F.R.C.S., Hon. Secretary of the Medical Staff.

Ulster Hospital for Children and Women, Templemore-avenue, Belfast (57 beds).—Clinical instruction to students in Diseases of Children, Gynæcology and Obstetrics. Special departments: Radiology and Actinotherapy, Eye, Ear, and Throat, V.D. Clinic and Antenatal Clinic. Gold Medal awarded annually. Two House Surgeons appointed from students of hospital.

Benn Ulster Eye, Ear and Throat Hospital, Clifton-street, 30 beds, and **Belfast Ophthalmic Hospital**, Great Victoria-street, 30 beds.—Practical demonstrations by the staff and occasional clinical lectures in the subjects of Ophthalmology, Otology, and Laryngology. Clinical instruction is given daily.

Belfast Fever Hospitals.—City Fever Hospital, Purdysburn (360 beds); Union Fever Hospital (200 beds). Clinical Classes are held during the winter and summer sessions. Post-graduate (D.P.H.) Classes are also held. Dr. A. Gardner Robb, Lecturer and Medical Superintendent.

Belfast Mental Hospital (Purdysburn Villa Colony) (1300 beds). University Lectures and clinics.

IRISH MEDICAL CORPORATIONS GRANTING DIPLOMAS.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND AND ROYAL COLLEGE OF SURGEONS IN IRELAND.

The Irish Conjoint Board requires of candidates the passage either of its own preliminary examination in the subjects of general education or proof that the candidate has passed one of the tests accepted by the General Medical Council as well as passing in the Pre-Registration Examinations in Chemistry and Physics and Biology.

Professional Examinations.—There are three professional examinations, the first of which cannot be passed earlier than the end of the second winter session, nor the final before the conclusion of full five years of medical study. Before being admitted to any of them the candidate must show that he has studied the different subjects in practice and theory for the requisite periods, certificates to this effect being accepted from the authorities of most of the recognised medical schools at home and abroad. The first examination deals with (*a*) Anatomy, and (*b*) Physiology and Histology. The second examination deals with (*a*) Pathology, (*b*) Materia Medica, Pharmacy, and Therapeutics and Ophthalmology, and may be taken separately.

Final Examination.—This is divided into three divisions, which cannot be completed until at least five years have passed in medical studies other than those for the Pre-Registration Examinations, and five years at least since the beginning of the curriculum. The divisions are (*a*) Medicine, including Fevers, Mental Diseases, and Diseases of Children; (*b*) Surgery, including Operative Surgery; (*c*) Midwifery, including Diseases of Women and Children, and the Practice of Vaccination.

Diploma in Psychological Medicine.—There are two examinations in connexion with this Diploma: Part I. consists of (*a*) Anatomy and Physiology of the Nervous System; (*b*) Psychology. Part II.: (*a*) Neurology, including Clinical and Pathological Neurology: (*b*) Psychological Medicine, including its legal relationships.

Further information can be obtained from the Secretary of the Committee of Management, Royal College of Surgeons, St. Stephen's Green.

is occupied by a Botanic Garden and a portion is at the disposal of the College Athletic Union. There are several student societies in the College, including a Biological Society. There are abundant facilities for research and Post-graduate work in the Chemistry, Physiology, and Pathology departments. There are ample facilities for Women Students. Further information can be obtained from the Registrar of the College.

Clinical Instruction is given in the Galway Tuberculosis Hospital and in the Galway Central and Fever Hospitals, containing on an average 350 patients.

CENTRAL HOSPITAL, GALWAY (300 beds).—In this completely renovated hospital, in addition to the Finer Surgical and Medical Departments, there are now Eye and Ear, Throat and Nose, Gynæcological and Obstetrical, Pathological, X Ray, Ultra-Violet Rays, and Electrical and Massage Departments. Students attend from University College, Galway. Medical and Surgical Clinics are held on alternate days during term. One Resident Physician and one Resident Surgeon are appointed every six months. Arrangements are being made for admission of Resident Students. The hospital is open to qualified medical men for post-graduate work.

QUEEN'S UNIVERSITY OF BELFAST.

There are six degrees in the Faculty of Medicine of the University—viz., Bachelor of Medicine (M.B.), Bachelor of Surgery (B.Ch.), Bachelor of Obstetrics (B.A.O.), Doctor of Medicine (M.D.), Master of Surgery (M.Ch.), and Master of Obstetrics (M.A.O.). The University also grants a Diploma in Public Health, particulars of which will be found in the University Calendar. The degrees of M.B., B.Ch., and B.A.O. are the primary degrees in the Faculty of Medicine, and are conferred at the same time and after the same course of study. No student is admitted to the final examination for these degrees until he has shown: (1) that he is a matriculated student of the University; (2) that he has completed the prescribed course of study in the Faculty of Medicine extending over a period of not less than five academic years from the date of his registration as a student of Medicine; (3) that he has passed the several examinations prescribed; (4) that he has attended in the University during three academic years at least the courses of study prescribed for such degrees (the Senate may accept, for not more than two academic years of the required five, courses of study pursued in any other University or School of Medicine approved by the Senate); and (5) that he has attained the age of 21 years. Every candidate for admission shall matriculate or fulfil such other test of fitness as may be prescribed by the Senate, or may be exempted from the matriculation examination by having passed similar examinations elsewhere. For information as to Scholarships and Prizes, inquiry should be made of the Secretary of the University.

Primary Degrees of M.B., B.Ch., B.A.O.—All candidates for these degrees must satisfy the examiners in the subjects of four examinations.

The First Medical Examination.—The subjects of this examination are Chemistry (Inorganic and Organic), Experimental Physics, Botany and Zoology. The examination will be divided into two parts which may be taken separately: I., Chemistry and Physics; II., Botany and Zoology.

The Second Medical Examination.—The subjects are Anatomy and Practical Anatomy, Physiology and Practical Physiology. Candidates who have previously passed the First Medical Examination may present themselves for this examination at the close of their second year.

The Third Medical Examination.—The subjects are: (1) Pathology and Practical Pathology; (2) Materia Medica, Pharmacology and Therapeutics; (3) Medical Jurisprudence; (4) Hygiene. Candidates who have previously passed the Second Medical Examination may present themselves for this examination at the close of the third year. Attendance on a course in any subject of the Third Medical Examination shall not entitle a student to a certificate of attendance unless he has previously passed in all the subjects of the Second Medical Examination.

The Fourth Medical Examination.—The subjects are: (1) Medicine; (2) Surgery; (3) Midwifery; (4) Ophthalmology and Otology. This examination may be taken in two parts: I., Systematic; II., Clinical, Practical and Oral. Candidates who have previously passed the Third Examination may present themselves for Part I. of the Fourth Examination at the close of the fourth year, provided that they have fulfilled the necessary requirements as to attendance, &c., on the courses of instruction in the subjects of examination. Candidates who have passed Part I. of this examination may present themselves for Part II. at the close of the fifth year, provided that they have fulfilled the necessary requirements as to hospital attendance on the various clinical courses in the subjects of examination. Parts I. and II. may be taken together at the close of the fifth year. Attendance on a course in any subject of the Fourth Medical Examination shall not entitle a student to a certificate of attendance unless he has passed in the subjects of the Second Medical Examination.

Degrees of M.D., M.Ch., and M.A.O.—These degrees are not conferred until the expiration of at least three academic years, or in the case of graduates of the University in Arts or Science of at least two academic years, after admission to the primary degrees in the Faculty of Medicine. Every candidate must show that in the interval he has pursued such courses of study, or been engaged in such practical work as may be prescribed. These degrees may be conferred by the Senate either (*a*) after an examination, which includes written, oral, clinical, and practical examinations; or (*b*) on the submission of a thesis or other evidence of original study or research, to be approved by the Faculty of Medicine after an oral or other examination of the candidate on the subject.

The Medical School.—The Donald Currie Chemical Buildings contain a lecture theatre, a preparation room, a chemical museum, a large class-room for elementary practical chemistry, laboratories for qualitative and quantitative analysis, rooms for water and gas analysis, dark room for photographic purposes and balance room, provided with all modern appliances. The Anatomical Department contains a large and well-lighted dissecting-room, a lecture-room, a professor's and demonstrator's room, a bone-room, and a laboratory for microscopic and photographic work. The Medical Museum is in the same building. The Jaffé Laboratories for Physiology comprise a lecture theatre, laboratories for practical work in chemical physiology, histology, and experimental physiology, and in addition small private research rooms, including balance, galvanometer, and centrifuge rooms. The J. C. White laboratories, recently founded, are fully equipped for research in biochemistry and bacteriology. The Musgrave Pathological Laboratory.—In this department opportunity is afforded for research in pathology and bacteriology. The department is in touch with most of the hospitals in Belfast, and there is an ample supply of material for investigation by graduates in morbid histology, clinical pathology, and the bacteriology of infectious diseases. A course in pathology or bacteriology is given to graduates, and members of this class have an opportunity of seeing the methods employed in the various investigations carried out in the department for the Public Health Committee of the Corporation in connexion with water-supply, sewage disposal, meat- and milk-supply, and the diagnosis of cases of infectious diseases. The certificate issued to members of the class in bacteriology qualifies for the D.P.H. degree. The Pharmaceutical Laboratory is fitted and equipped for the work of practically instructing students in the compounding and dispensing of medicines.

Clinical Instruction.—The following institutions are recognised by the University as affording proper opportunities for clinical instruction: the Royal Victoria Hospital, the Mater Infirmorum Hospital, the Union Hospitals, the Belfast Hospital for Sick Children, the Belfast Maternity, the Ulster Hospital for Women and Children, the Ulster Eye, Ear, and Throat Hospital, the Belfast Ophthalmic Hospital, the Purdysburn Fever Hospital, and the Belfast District Lunatic Asylum. Complete information can be obtained from the respective Secretaries.

Royal Victoria Hospital. Belfast, 436 beds.—Students eligible for McGrath, McQuitty, Malcolm, Coulter Smyth and Elwood Scholarships aggregate annual value £185. Twelve House Surgeons and House Physicians. Thirty-six resident pupilships, three months each, annually for Senior Students, of which a proportion is allotted to Women Students, Special Departments for Radiology, Clinical Pathology, V.D., Dermatology, Gynæcology, Vaccine Therapy, Electrocardiography, Dentistry.

Mater Infirmorum Hospital, Belfast.—This hospital contains 270 beds and is open at all hours for the reception of accidents and urgent cases. Clinical instruction is given daily by Physicians and Surgeons. Surgical operations are performed daily. The out-patient departments in Medicine and Surgery, also the special dispensaries for Gynæcology, Ear, Eye and Throat, Electrotherapeutics, Venereal Diseases are very largely attended and afford valuable opportunities to students for the study of those subjects. A House Physician and two House Surgeons are elected every six months. Resident pupils are admitted as the vacancies arise. Three Exhibitions and a Gold Medal are competed for annually in June. Certificates of attendance upon this hospital are recognised by all the Universities and licensing bodies in the United Kingdom.

Belfast Infirmary and Hospital (1600 beds).—Clinical courses are given quarterly, and a course for D.P.H. in Hospital. Intern Venereal Clinic in Infirmary under Corporation scheme. Maternity Hospital recognised for Practical Midwifery training. Particulars may be obtained on application to the Hon. Sec. Visiting Medical Staff. Certificate of vaccination class recognised by Local Government Board. There is a department for Cancer with 32 beds, and X Ray and Bacteriological Departments.

The Belfast Hospital for Sick Children, Queen-street (45 beds).—Clinical instruction is given in this hospital. During the Winter Session two Courses of Lectures are delivered on the Medical and Surgical Diseases incidental to Infancy and Childhood. Demonstrations in Ophthalmology and Pathology are given, and ample opportunities are afforded in the wards and in the Out-patient Department for gaining a practical and theoretical knowledge of the diseases of Infancy and Childhood. This Hospital grants Certificates in Diseases of Children, which are recognised by the various Examining Bodies. Certificates are also granted for post-graduate study. A Gold Medal is offered for competition at the close of the session.

Maternity Hospital, Townsend-street, Belfast.—Twenty-five beds in constant occupation, and exclusively devoted to Midwifery and Antenatal conditions. There is also a large district. The Queen's University of Belfast have erected a Students' Hostel in connexion with the Hospital where six Students and Post-graduates are received each month. The University Tutor in Obstetrics resides in the Hostel and Students conduct their cases under his supervision. There is a large Antenatal Department and a Department for Venereal Diseases. Communications should be made to C. H. G. Macafee, M.B., F.R.C.S., Hon. Secretary of the Medical Staff.

Ulster Hospital for Children and Women, Templemore-avenue, Belfast (57 beds).—Clinical instruction to students in Diseases of Children, Gynæcology and Obstetrics. Special departments: Radiology and Actinotherapy, Eye, Ear, and Throat, V.D. Clinic and Antenatal Clinic. Gold Medal awarded annually. Two House Surgeons appointed from students of hospital.

Benn Ulster Eye, Ear and Throat Hospital, Clifton-street, 30 beds, and Belfast Ophthalmic Hospital, Great Victoria-street, 30 beds.—Practical demonstrations by the staff and occasional clinical lectures in the subjects of Ophthalmology, Otology, and Laryngology. Clinical instruction is given daily.

Belfast Fever Hospitals.—City Fever Hospital, Purdysburn (360 beds); Union Fever Hospital (200 beds). Clinical Classes are held during the winter and summer sessions. Post-graduate (D.P.H.) Classes are also held. Dr. A. Gardner Robb, Lecturer and Medical Superintendent.

Belfast Mental Hospital (Purdysburn Villa Colony) (1300 beds). University Lectures and clinics.

IRISH MEDICAL CORPORATIONS GRANTING DIPLOMAS.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND AND ROYAL COLLEGE OF SURGEONS IN IRELAND.

The Irish Conjoint Board requires of candidates the passage either of its own preliminary examination in the subjects of general education or proof that the candidate has passed one of the tests accepted by the General Medical Council as well as passing in the Pre-Registration Examinations in Chemistry and Physics and Biology.

Professional Examinations.—There are three professional examinations, the first of which cannot be passed earlier than the end of the second winter session, nor the final before the conclusion of full five years of medical study. Before being admitted to any of them the candidate must show that he has studied the different subjects in practice and theory for the requisite periods, certificates to this effect being accepted from the authorities of most of the recognised medical schools at home and abroad. The first examination deals with (*a*) Anatomy, and (*b*) Physiology and Histology. The second examination deals with (*a*) Pathology, (*b*) Materia Medica, Pharmacy, and Therapeutics and Ophthalmology, and may be taken separately.

Final Examination.—This is divided into three divisions, which cannot be completed until at least five years have passed in medical studies other than those for the Pre-Registration Examinations, and five years at least since the beginning of the curriculum. The divisions are (*a*) Medicine, including Fevers, Mental Diseases, and Diseases of Children; (*b*) Surgery, including Operative Surgery; (*c*) Midwifery, including Diseases of Women and Children, and the Practice of Vaccination.

Diploma in Psychological Medicine.—There are two examinations in connexion with this Diploma: Part I. consists of (*a*) Anatomy and Physiology of the Nervous System; (*b*) Psychology. Part II.: (*a*) Neurology, including Clinical and Pathological Neurology; (*b*) Psychological Medicine, including its legal relationships.

Further information can be obtained from the Secretary of the Committee of Management, Royal College of Surgeons, St. Stephen's Green.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

The College issues its Licences in Medicine and in Midwifery to practitioners whose names appear on the Medical Register of the United Kingdom.

The Licence in Medicine.—The subjects of examination are: Practice of Medicine, Clinical Medicine, Pathology, Medical Jurisprudence, Midwifery, Hygiene, and Therapeutics.

The Licence in Midwifery.—Candidates must produce certificates of registration. A registered medical practitioner of five years' standing may be exempted from the examination by printed questions.

The Membership.—Examinations for Membership are held in February, June, and November.

The Fellowship.—Fellows are elected by ballot. Applicants must have been a Member of the College for at least one year and must have attained the age of 27 years.

Further particulars can be obtained from the Registrar of the Royal College of Physicians of Ireland, 6, Kildare-street, Dublin.

ROYAL COLLEGE OF SURGEONS IN IRELAND.

The College issues its Licence in Surgery to practitioners whose names are entered either on the Medical Register for the United Kingdom, the Colonial Medical Register, or the Foreign Medical Register of the year in which he presents himself for examination, and who satisfies the Council that he has passed through a course of study and Examinations equivalent to those required by the Regulations of the Irish Conjoint Board.

Candidates are examined in General Surgery (paper and oral), Clinical Surgery, Surgical Pathology (oral), Operative Surgery, Surgical Anatomy (paper), and Ophthalmic and Aural Surgery (clinical).

Diploma in Midwifery.—A diploma in Midwifery is granted after examination to persons possessing a registrable qualification.

Fellowship Examinations.—Candidates for the Fellowship shall make application to the President and Council to be admitted to examination. They are required to pass two examinations—Primary and Final. Candidates may present themselves for the Final Examination immediately after passing the Primary part, provided they have complied with the necessary regulations. The subjects for the Primary Examination are (*a*) Anatomy, including Dissections; and (*b*) Physiology and Histology. The subjects for the Final Examination are Surgery, including Surgical Anatomy and Pathology. For admission to the Final Examination the candidate must have passed the Primary Examination, and must be a Licentiate or Graduate in Surgery of a university or licensing body recognised by the General Medical Council; all such candidates must not be less than 25 years of age.

Further particulars can be obtained from the Registrar of the College, Stephen's-green West, Dublin.

ROYAL COLLEGE OF SURGEONS IN IRELAND (SCHOOLS OF SURGERY).—The schools of surgery are attached by Charter to the Royal College of Surgeons and have existed as a department of the College for over a century. They are carried on within the College buildings and are specially subject to the supervision and control of the Council, who are empowered to appoint and remove the professors and to regulate the methods of teaching pursued. The buildings have been reconstructed, the capacity of the dissecting-room nearly trebled, and special pathological, bacteriological, public health, and pharmaceutical laboratories fitted with the most approved appliances in order that students may have the advantage of the most modern methods of instruction. The entire building is heated by hot-water pipes and lighted throughout by the electric light. Winter Session commences in October; Summer Session in April. Scholarships and Prizes; Carmichael Scholarship, £15; Mayne Scholarship, £8; Stoney Memorial gold medal; Operative Surgery, gold and silver medals; Pierefoy Memorial Prize, value £150; Barker Prize, £26 5s.; H. Macnaughton-Jones gold medal in Obstetrics and Gynæcology; and class prizes and medals. Prospectuses and guide for medical students can be obtained post free on written application to the Registrar, Royal College of Surgeons, Stephen's-green W., Dublin.

APOTHECARIES' HALL OF IRELAND.*

The Licence of this Hall is granted to students who present certificates of having fully completed the course of study as laid down in the curriculum and who pass the necessary examinations. The diploma of the Hall entitles the holder to be registered as a practitioner in medicine, surgery, and midwifery, with also the privileges of the Apothecary's Licence.

Candidates must pass two Professional Examinations, called the Primary Examination and the Final Examination, which are conducted at separate times, partly in writing, and partly practically and orally. The Primary and Final Professional Examinations are held twice a year—viz., in June and November, or such other dates as may be determined.

Candidates who produce satisfactory evidence of having passed an examination for a Degree or Licence in Medicine, conducted by any University or Royal College in the British Empire, or by any Foreign University whose Degrees are recognised in the Foreign List of the Medical Register, will be exempted from the Primary Examination.

The subjects for Part I. of the Primary Examination are: Anatomy, Physiology and Histology, including Bio-Chemistry; and for Part II., Materia Medica and Pharmacy, Pathology, and Medical Jurisprudence and Hygiene.

For the Final Examination the subjects are: (*a*) Medicine and Clinical Medicine and Clinical Methods. (*b*) Surgery—Clinical, Ophthalmic and Operative; and Surgical Anatomy. (*c*) Midwifery and Gynæcology, and Practical Pharmacy and Materia Medica (if not taken at Intermediate Examination).

Each candidate before receiving his diploma must produce evidence that he has attained the age of 21 years. The details of the course of education required and syllabus of the examinations will be supplied by the Registrar at 95, Merrion-square, Dublin.

WE take this opportunity of thanking the officials of Government Departments and the Deans and Secretaries of the various institutions for their kind coöperation in enabling us to bring the information contained in our Students' Number up to date.

GUILD OF ST. LUKE.

THE Guild of St. Luke was founded over 60 years ago by a few medical students, chiefly to meet their own religious needs. It now makes a wider appeal, and its membership is open to all students and practitioners of medicine, both men and women, who are members of the Church of England, the clergy of which are eligible as Clerical Associates. The Chapter meets in every month of each term, and a festival service is held yearly at St. Luke's tide, usually at St. Paul's or Westminster Abbey. This year the service will be at the Abbey. Besides the parent Guild, there are a Women's Ward and a Hospital Student's Branch in London. There are also a Midland Counties Ward and a Cambridge Ward. Particulars of the objects and activities of the Guild and forms of application for membership can be obtained from the Secretary of the Guild of St. Luke, Room B.B., King's College, Strand, W.C.2.

THE LANCET.

LONDON: SATURDAY, AUGUST 25, 1928.

THE READJUSTMENT OF THE MEDICAL CURRICULUM.

DURING the past 12 months no public aspect of the calling of medicine has been seriously altered, no legal enactment has introduced any big departure into professional life, and no pronouncements of the General Medical Council have resulted in any radical changes of the curriculum. The tendency in London to segregate medical study as between men and women students may be only a passing phase. The numbers of the medical profession in practice have remained virtually stable, while the same can be said in general terms of the population of the Empire, so that no situation has been created attributable either to an excessive or deficient number of our calling; there is still keen competition in some quarters, and there is still much room for the right man in others. But the static conditions do not imply any pause in progress, for the absence of marked episode has synchronised with much steady work along educational lines previously laid down.

For example, there may be cited the advance made throughout the country towards the readjustment of the medical curriculum in accordance with the resolutions of the General Medical Council passed some six years ago. These resolutions came into force on Jan. 1st, 1923, and their result has been the occurrence of important deliberations in the Council, the various questions arising being dealt with in reports by the Education Committee, and made the subject of correspondence between the Committee and the centres of medical education. The gist of the work of the Council has been to arrange an orderly and common course of study as a minimum standard for the centres, while safeguarding entry to the profession by an examination ensuring that before registration the student must have passed a recognised examination in general education and, in addition, an examination in elementary chemistry and physics either conducted by, or recognised by, one of the licensing bodies. The registered student will in this way, theoretically, have broken ground in two basic directions of his professional work while being generally equipped up to a professional standard. After registration the resolutions of the Council in regard to professional education provide that the period of professional study between the date of registration as a medical student and the date of the final examination for any diploma entitling to registration should extend over not less than five academic years. That is to say, the student should have passed the examination in general education and the pre-registration examination and have commenced study at a medical school before he can be registered, after which the time required is a minimum of five academic years, or, say, 57 months. The proposal for a pre-registration examination was of course made with the object of lightening the preliminary portion of the medical course, the assistance of various educational agencies, particularly the higher secondary schools, being called in to assist in laying a scientific foundation for medical students. This reform was advocated in our columns and elsewhere many years ago, but failed to find support owing to the feeling that the unequal distribution in the kingdom of these secondary schools would act prejudicially for some of the students, but a wider and wiser view now obtains. Other primary and additional resolutions of the Council dealt with the course and examinations of the whole curriculum, suggesting the ground that must be covered by general and special study and the best way in which to allot the time available, when the whole document, in the form of an Interim Report of the Education Committee, was submitted to the various educational centres, who were invited to make comment upon them. They were asked, in fact, to indicate how far their existing patterns of training complied with those advocated by the Council, and the resulting replies disclosed both a satisfactory state of affairs in being and a general willingness to meet the new requirements—this not only in respect of the pre-registration examination and the arrangement of the five years' course, but along many special lines of academic and practical instruction. The replies of the licensing bodies were later published in the Final Report of the Education Committee and the information summarised in this issue of THE LANCET is in accord with them.

Those, then, who are now joining our ranks enter a profession where the steps of their training will be guided with a precision that until quite recently was unknown. This lucid charting of the voyage will be found valuable to many, and indeed to all, for both industry and attention will have to be sustained by them for an extended period. The Council is to be congratulated upon the outcome of delicate and protracted labours in readjusting the curriculum; but it may be pointed out that the whole spirit of these labours, as well as their issue at the present moment, proves that the curriculum will always need readjustment in accordance with the developments of medical science. For example, throughout the latest pourparlers no particular stress appears to have been laid either by the Council or by the licensing bodies on the difficult subject of practical instruction in midwifery, and during the period that has elapsed since the Final Report of the Education Committee on readjustment was published, this question has become burning. Among the various subjects specially recommended for study by the Council, tuberculosis, venereal diseases, and antenatal conditions appeared to the Education Committee to be of particular importance, so much so that, at the request of the Committee, Sir GEORGE NEWMAN prepared a personal report on the subject, which has now been circulated to the licensing bodies. Progress along these lines should help to prevent the sad divergence between preventive and curative medicine. All these licensing bodies provide systematic instruction in midwifery over a fair proportion of the five years' course, and all students are compelled, in addition, to conduct an adequate number of labours within a recognised institution or, under supervision, as clinical visitants at the homes of the patients. But undoubtedly more will be expected. The intentions of all the licensing bodies are admirable, but it is common knowledge that the midwifery training of students, speaking generally, requires strengthening on the practical side. This is a circumstance which will have to be borne in mind when the methods for securing coöperation between the voluntary hospitals and the county institutions are under discussion—as they will immediately be; while the new diploma of the Society of Apothecaries of London demonstrates that a higher standard of obstetric and gynæcological accomplishment is necessary. Midwifery has always been the keystone of general practice.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

The College issues its Licences in Medicine and in Midwifery to practitioners whose names appear on the Medical Register of the United Kingdom.

The Licence in Medicine.—The subjects of examination are: Practice of Medicine, Clinical Medicine, Pathology, Medical Jurisprudence, Midwifery, Hygiene, and Therapeutics.

The Licence in Midwifery.—Candidates must produce certificates of registration. A registered medical practitioner of five years' standing may be exempted from the examination by printed questions.

The Membership.—Examinations for Membership are held in February, June, and November.

The Fellowship.—Fellows are elected by ballot. Applicants must have been a Member of the College for at least one year and must have attained the age of 27 years.

Further particulars can be obtained from the Registrar of the Royal College of Physicians of Ireland, 6, Kildare-street, Dublin.

ROYAL COLLEGE OF SURGEONS IN IRELAND.

The College issues its Licence in Surgery to practitioners whose names are entered either on the Medical Register for the United Kingdom, the Colonial Medical Register, or the Foreign Medical Register of the year in which he presents himself for examination, and who satisfies the Council that he has passed through a course of study and Examinations equivalent to those required by the Regulations of the Irish Conjoint Board.

Candidates are examined in General Surgery (paper and oral), Clinical Surgery, Surgical Pathology (oral), Operative Surgery, Surgical Anatomy (paper), and Ophthalmic and Aural Surgery (clinical).

Diploma in Midwifery.—A diploma in Midwifery is granted after examination to persons possessing a registrable qualification.

Fellowship Examinations.—Candidates for the Fellowship shall make application to the President and Council to be admitted to examination. They are required to pass two examinations—Primary and Final. Candidates may present themselves for the Final Examination immediately after passing the Primary part, provided they have complied with the necessary regulations. The subjects for the Primary Examination are (*a*) Anatomy, including Dissections; and (*b*) Physiology and Histology. The subjects for the Final Examination are Surgery, including Surgical Anatomy and Pathology. For admission to the Final Examination the candidate must have passed the Primary Examination, and must be a Licentiate or Graduate in Surgery of a university or licensing body recognised by the General Medical Council; all such candidates must not be less than 25 years of age.

Further particulars can be obtained from the Registrar of the College, Stephen's-green West, Dublin.

ROYAL COLLEGE OF SURGEONS IN IRELAND (SCHOOLS OF SURGERY).—The schools of surgery are attached by Charter to the Royal College of Surgeons and have existed as a department of the College for over a century. They are carried on within the College buildings and are specially subject to the supervision and control of the Council, who are empowered to appoint and remove the professors and to regulate the methods of teaching pursued. The buildings have been reconstructed, the capacity of the dissecting-room nearly trebled, and special pathological, bacteriological, public health, and pharmaceutical laboratories fitted with the most approved appliances in order that students may have the advantage of the most modern methods of instruction. The entire building is heated by hot-water pipes and lighted throughout by the electric light. Winter Session commences in October; Summer Session in April. Scholarships and Prizes; Carmichael Scholarship, £15; Mayne Scholarship, £8; Stoney Memorial gold medal; Operative Surgery, gold and silver medals; Piercefoy Memorial Prize, value £150; Barker Prize, £26 5s.; H. Macnaughton-Jones gold medal in Obstetrics and Gynæcology; and class prizes and medals. Prospectuses and guide for medical students can be obtained post free on written application to the Registrar, Royal College of Surgeons, Stephen's-green W., Dublin.

APOTHECARIES' HALL OF IRELAND.*

The Licence of this Hall is granted to students who present certificates of having fully completed the course of study as laid down in the curriculum and who pass the necessary examinations. The diploma of the Hall entitles the holder to be registered as a practitioner in medicine, surgery, and midwifery, with also the privileges of the Apothecary's Licence.

Candidates must pass two Professional Examinations, called the Primary Examination and the Final Examination, which are conducted at separate times, partly in writing, and partly practically and orally. The Primary and Final Professional Examinations are held twice a year—viz., in June and November, or such other dates as may be determined.

Candidates who produce satisfactory evidence of having passed an examination for a Degree or Licence in Medicine, conducted by any University or Royal College in the British Empire, or by any Foreign University whose Degrees are recognised in the Foreign List of the Medical Register, will be exempted from the Primary Examination.

The subjects for Part I. of the Primary Examination are: Anatomy, Physiology and Histology, including Bio-Chemistry; and for Part II., Materia Medica and Pharmacy, Pathology, and Medical Jurisprudence and Hygiene.

For the Final Examination the subjects are: (*a*) Medicine and Clinical Medicine and Clinical Methods. (*b*) Surgery—Clinical, Ophthalmic and Operative; and Surgical Anatomy. (*c*) Midwifery and Gynæcology, and Practical Pharmacy and Materia Medica (if not taken at Intermediate Examination).

Each candidate before receiving his diploma must produce evidence that he has attained the age of 21 years. The details of the course of education required and syllabus of the examinations will be supplied by the Registrar at 95, Merrion-square, Dublin.

WE take this opportunity of thanking the officials of Government Departments and the Deans and Secretaries of the various institutions for their kind coöperation in enabling us to bring the information contained in our Students' Number up to date.

GUILD OF ST. LUKE.

THE Guild of St. Luke was founded over 60 years ago by a few medical students, chiefly to meet their own religious needs. It now makes a wider appeal, and its membership is open to all students and practitioners of medicine, both men and women, who are members of the Church of England, the clergy of which are eligible as Clerical Associates. The Chapter meets in every month of each term, and a festival service is held yearly at St. Luke's tide, usually at St. Paul's or Westminster Abbey. This year the service will be at the Abbey. Besides the parent Guild, there are a Women's Ward and a Hospital Student's Branch in London. There are also a Midland Counties Ward and a Cambridge Ward. Particulars of the objects and activities of the Guild and forms of application for membership can be obtained from the Secretary of the Guild of St. Luke, Room B.B., King's College, Strand, W.C.2.

---

* No returns.

As in the case of the medical branch, 20 per cent. of the rates of full pay, unemployed pay, half pay, and retired pay introduced in 1919 is considered as due to the high cost of living in 1919 and subject to change periodically either upwards or downwards according as the cost of living rises or falls. The first revision took place in July, 1924, when all the rates were reduced by approximately 5½ per cent., the second revision took place in July, 1927, when all rates were reduced by ½ per cent., and further revisions are due every three years—i.e., in July, 1930, and so on.

ARMY MEDICAL SERVICE.

ROYAL ARMY MEDICAL CORPS.

THE publication of the Royal Warrant of 1926 has removed many of the grievances of officers of the Corps, and this Service can again be recommended as a career to young medical men. Competitive examinations for regular commission, which have been in abeyance for some time, will again be held half-yearly in January and July. These examinations in medicine and surgery are entirely of a clinical and practical character, partly written and partly oral.

The regulations for admission giving full details should be obtained from the Permanent Under Secretary of State (A.M.D. 1), War Office, Whitehall, London, S.W. 1, and carefully studied. A personal interview with a representative of the Director-General, Army Medical Services, is readily obtainable.

The rates of pay and allowances are good; the opportunities of post-graduate study are generous, and the work is varied, responsible, and interesting. The gratuities after certain periods of service enable an officer should he so desire to leave the Service with a capital sum large enough to go a long way towards re-establishing himself in civil life, and, further, the knowledge of the world and the comradeship of his fellow officers that he has gained in the Army will be of no small value to him.

New entrants are commissioned in the rank of Lieutenant, and the first six months of service are spent on probation, during which time they undergo, in addition to their Military training at the Royal Army Medical Corps Depôt at Aldershot, a probationary course at the Royal Army Medical College in London in Hygiene, Pathology, Tropical Medicine, Military Surgery, Recruiting, the prevention and treatment of Venereal Disease, and the elements of Army Administration. At the end of this course, and after qualifying at the necessary examinations, their commissions are confirmed, and they take their places in seniority according to the total marks obtained at all examinations up to that date. Officers Training Corps service with possession of Certificates "A" or "B" (Medical) carry a definite value in marks in this total.

An entrant who is holding or about to hold at the time of the entrance examination a resident House Appointment at an approved Civil Hospital may be seconded while holding such an appointment up to a maximum period of 12 months. A candidate who has held such an appointment within six months of entry may be granted an antedate up to 12 months in respect of the period the appointment was held. This secondment and antedate counts in all respects as commissioned service, except that pay will not be issued for that period.

After a total period of one year's service at home the young officer goes abroad, probably to India, for his first tour of foreign service. Here he gains his first practical experience of tropical disease and tropical hygiene, and possibly his first experience of active service on the frontiers of India. His tour abroad lasts five years, with probably six months' leave home during that time. On returning home the R.A.M.C. officer has the opportunity to decide whether he will remain in the Corps or accept the gratuity of £1000 after seven years' service, and try his fortune in civil life. If he elects to remain, he will, between his eighth and twelfth year of service, undergo a course of post-graduate study at the Royal Army Medical College and the London Hospitals of five months' duration, followed by a course of study of a special subject selected by himself, provided he has shown special aptitude in the post-graduate course or during his previous service. During this period of study he remains on full pay, and the fees for the courses are paid by the State. When qualified in his special subject, the officer becomes entitled to specialist pay at 5s. per day when holding a specialist appointment. After this post-graduate course the officer probably proceeds abroad again and promotion to Major rapidly ensues, and from that time onward the officer receives regular successive increases of pay, and is eligible for additional and charge pay as well. The Directorates of Hygiene and Pathology and the appointment of two serving officers as Consultants in Medicine and Surgery have been instituted and have proved a marked success, all these appointments being of the rank of Colonel or Major-General.

Under *these conditions* the possibilities for good workers are very great in the Royal Army Medical Corps. There is scope for original research in tropical

* Pay Warrant rates as amended by A.O. 196/26 less 6 per cent. from July 1st, 1927, vide A.O. of 1927. The Pay Warrant rates are subject to revision to an extent not exceeding 20 per cent. according to variation in the cost of living. The next revision takes place from July 1st, 1930.

† Rates of allowances vary from time to time and issues are subject to conditions laid down in the Allowance Regulations.

The Medical Services.

ROYAL NAVAL MEDICAL SERVICE.

CHOOSING A CAREER.

To a man of the proper temperament, a career as a medical officer in the Royal Navy offers very definite attractions. In these days his professional knowledge will most certainly not rust in this Service, and in the naval hospitals he will have opportunities of practising every branch of his profession except gynæcology. He can obtain one of 60 paid specialist appointments, and these fall under the headings of medicine; surgery; bacteriology and pathology; hygiene; diseases of eyes, nose, ear, and throat; radiology; anæsthetics; genito-urinary and venereal diseases; and the principles of physical training. He will be encouraged to work hard and will have chances to play hard. The Navy was possibly the first public Service to realise the value of recreation, and puts its provision into practice, and there is no branch of athletics or field sports in which the naval officer does not have an opportunity of engaging in, in a home port or on a foreign station. He will see the world largely and often under ideal conditions. A naval medical officer who is a good doctor, keen on work and play, and unselfish, invariably becomes everybody's friend. The naval officer and the bluejacket are quick to recognise a medical officer who is keen on his work, thoughtful for his patients, and one who strives after improving the health of the Navy. And nowhere can one find more delightful friends than in the Navy.

There is to-day much to encourage the right type of medical man to join the Navy. The Admiralty allow an ante-date of one year to those naval surgeons who before entry held a resident appointment for one year at certain large hospitals, and encourage men to take higher qualifications. Opportunities to this end are freely given, when the exigencies of the Service will permit, and medical officers are able to take post-graduate courses prior to sitting for these higher examinations. As a matter of fact, a large number of naval medical officers since joining the Navy have taken various honour qualifications as well as special diplomas, and it is recognised that this is good for the Navy as well as for the officer. In the large naval hospitals, the medical, surgical, and specialist work is of a high standard. It is exacting, but it is the aim of the Admiralty to arrange appointments as far as possible so that medical officers have an opportunity of alternating their work both at home and abroad, and ashore and afloat. And to give naval surgeons full opportunities for professional work the general and specialist courses have been increased in number so that, as far as possible, every officer shall have a course of instruction of not less than four months' duration every four years. The number of specialists allowed is now 60 instead of 46, and the specialist allowance is 5*s.* a day instead of 2*s.* 6*d.* a day. The establishment of surgeon captains has been increased from 16 to 20.

The total number of medical officers in the Navy is 402, and every recent improvement has been made towards giving increased opportunities of advancement to the best men, in their science, in research, and in organisation. He has opportunities to emulate some of the great naval physicians and surgeons of the past.

Pay.

The cost of living in the Navy is cheap, and an officer can live on his pay and enjoy life if he is not extravagant, especially if he does not embark in matrimony too early. A small amount of private means goes much further in the Navy than in civil life. The three vital points—pay, prospects, and promotion—of the naval medical officer can be grasped by referring to the following clear and brief table.

FULL PAY.

		£		£	
SURGEON LIEUTENANT (short service and permanent service)	from	152	to	499	per annum.
SURGEON LIEUTENANT-COMMANDER (promoted after six years' service)..	,,	600	to	630	,,
SURGEON COMMANDER (promoted after a further six years' service)..	,,	772	to	976	,,
SURGEON CAPTAIN (promoted by selection)	,,	1116	to	1372	,,
SURGEON REAR-ADMIRAL (promoted by selection)		1800			
MEDICAL DIRECTOR-GENERAL (Surgeon Vice-Admiral) ..		2350			

Allowances.

Allowances when in charge of hospitals and sick-quarters ..	10*s.* and 5*s.* per diem.
Sixty Specialist allowances of ..	5*s.* per diem.
Allowances to Senior Medical Officers in flag ships ..	5*s.* and 2*s.* 6*d.* per diem.

Accelerated promotion can be gained under certain conditions; there are also, on certain occasions, servant's allowance, provision allowance, and lodging allowance.

PENSION.

	Maximum retired pay.			
SURGEON VICE-ADMIRAL ..	£1123 per annum, on vacating office.			
SURGEON REAR-ADMIRAL ..	£950 per annum, at age of 60.			
SURGEON CAPTAIN	£846	,,	,,	55.
SURGEON COMMANDER	£564	,,	,,	50.
SURGEON LIEUTENANT-COMMANDER AND SURGEON LIEUTENANT	£423	,,	,,	45.

Gratuities on Retirement.

Below age of 45, officers receive gratuities on retirement on the following scale:—

				£
After	4	years' service	.. ..	500
,,	8	,, ,,	.. ..	1000
,,	12	,, ,,	.. ..	1500
,,	18	,, ,,	.. ..	2250

The extra allowances alluded to in the table are not to be looked upon as very exceptional. About a quarter of the medical officers of the Navy are drawing extra allowances. Of recent years medical officers have been admitted into the Navy without entrance examination and for short service with the option of turning over to the permanent service, but it is anticipated that it will not be long before the Admiralty will revert to the old-established system of entrance by competitive examination twice a year in batches of about ten officers.

DENTAL BRANCH.

The Naval Dental Service offers similar opportunities to qualified dental surgeons except that higher rank than that of the recently instituted Surgeon Captain (D) is not open to them. They are provided with suitable surgery accommodation equipped with modern appliances and supplied with all material required for their work, and there is every opportunity for them to maintain a high standard of professional skill.

Candidates are required to produce certificates of birth, registration, and of character, and must be physically fit for active service anywhere. An outfit allowance of £50 is payable to officers finally entered and commissioned. The rank of Surgeon Lieutenant-Commander (D) is attained o[illegible] six years' satisfactory service. [illegible] on Commander (D) and Surgeon Cap[illegible] de strictly by selection from the rank next below and are confined to officers who prove fitted in every respect for these ranks. The present establishment of dental officers is: 1 Surgeon Captain (D), 3 Surgeon Commanders (D), 60 Surgeon Lieutenant-Commanders (D) and Surgeon Lieutenants (D).

Provision has been made for candidates who, at the time of passing the examination, hold or are about to hold an appointment as Dental Officer in a recognised Civil Hospital. The time concerned, provided it does not exceed six months, may reckon for increase of full pay while on the active list. Surgeon Lieutenant-Commanders (D) of over two years' seniority will be eligible for a three months' Post-graduate Course while borne on full pay.

As in the case of the medical branch, 20 per cent. of the rates of full pay, unemployed pay, half pay, and retired pay introduced in 1919 is considered as due to the high cost of living in 1919 and subject to change periodically either upwards or downwards according as the cost of living rises or falls. The first revision took place in July, 1924, when all the rates were reduced by approximately 5½ per cent., the second revision took place in July, 1927, when all rates were reduced by ½ per cent., and further revisions are due every three years—i.e., in July, 1930, and so on.

ARMY MEDICAL SERVICE.

ROYAL ARMY MEDICAL CORPS.

THE publication of the Royal Warrant of 1926 has removed many of the grievances of officers of the Corps, and this Service can again be recommended as a career to young medical men. Competitive examinations for *regular commission*, which have been in abeyance for some time, will again be held *half-yearly in January and July*. These examinations in medicine and surgery are entirely of a clinical and practical character, partly written and partly oral.

The regulations for admission giving full details should be obtained from the Permanent Under Secretary of State (A.M.D. 1), War Office, Whitehall, London, S.W. 1, and carefully studied. A personal interview with a representative of the Director-General, Army Medical Services, is readily obtainable.

The rates of pay and allowances are good; the opportunities of post-graduate study are generous, and the work is varied, responsible, and interesting. The gratuities after certain periods of service enable an officer should he so desire to leave the Service with a capital sum large enough to go a long way towards re-establishing himself in civil life, and, further, the knowledge of the world and the comradeship of his fellow officers that he has gained in the Army will be of no small value to him.

New entrants are commissioned in the rank of Lieutenant, and the first six months of service are spent on probation, during which time they undergo, in addition to their Military training at the Royal Army Medical Corps Depôt at Aldershot, a probationary course at the Royal Army Medical College in London in Hygiene, Pathology, Tropical Medicine, Military Surgery, Recruiting, the prevention and treatment of Venereal Disease, and the elements of Army Administration. At the end of this course, and after qualifying at the necessary examinations, their commissions are confirmed, and they take their places in seniority according to the total marks obtained at all examinations up to that date. Officers Training Corps service with possession of Certificates "A" or "B" (Medical) carry a definite value in marks in this total.

An entrant who is holding or about to hold at the time of the entrance examination a resident House Appointment at an approved Civil Hospital may be seconded while holding such an appointment up to a maximum period of 12 months. A candidate who has held such an appointment within six months of entry may be granted an antedate up to 12 months in respect of the period the appointment was held. This secondment and antedate counts in all respects as commissioned service, except that pay will not be issued for that period.

After a total period of one year's service at home the young officer goes abroad, probably to India, for his first tour of foreign service. Here he gains his first practical experience of tropical disease and tropical hygiene, and possibly his first experience of active service on the frontiers of India. His tour abroad lasts five years, with probably six months' leave home during that time. On returning home the R.A.M.C. officer has the opportunity to decide whether he will remain in the Corps or accept the gratuity of £1000 after seven years' service, and try his fortune in civil life. c.s. = commissioned service.

* Pay Warrant rates as amended by A.O. 196/26 less 6 per cent. from July 1st, 1927, vide A.O. of 1927. The Pay Warrant rates are subject to revision to an extent not exceeding 2½ per cent. according to variation in the cost of living. The next revision takes place from July 1st, 1930.

† Rates of allowances vary from time to time and issues are subject to conditions laid down in the Allowance Regulations.

disease, in preventive medicine, and in bacteriology, as well as in the large clinical field open to the specialist in Medicine, Surgery or Gynæcology, in Venereal Disease, and in Ophthalmology. Child welfare is also undertaken systematically by officers of the Royal Army Medical Corps.

At the same time instruction in administration is continuous. The Royal Army Medical Corps is essentially organised for war, and one of the lessons of the Great War was that trained administrators must exist to enable the fullest benefit to be obtained from professional talent. Many appointments carrying administrative responsibility are open to those officers who display capacity for this duty. All officers must be prepared to undertake command and to have a knowledge of Army administration, especially in war. Equally important is the technical training of the Non-commissioned Officers and men of the Corps in such "trades" as Trained Nurse, Nursing Orderly, Masseur, Radiographer, Operating Room Assistant, Laboratory Assistant, Hospital Cook, Dispenser, &c. This training is carried out by the Officers and Nursing Sisters, and opens a large field for those who have ability in lecturing and teaching as well as the power of influencing men.

Promotion.

Promotion takes place automatically to Captain after 3½ years, and to Major after 12 years' service, provided the officer is qualified and recommended for promotion. Promotion to the higher ranks is by selection from those senior in the rank below, but special promotion by brevet or otherwise is open to officers of the Royal Army Medical Corps.

Additional Pay and Charge Pay for R.A.M.C. Officers.

(1) Officer not above the rank of lieutenant-colonel, while acting as specialist in a post considered by Our Army Council to merit the grant of additional pay, according to subjects or groups of subjects as under.

Operative Surgery, advanced; Medicine; Ophthalmology; Gynæcology and Midwifery; Dermatology, and Venereal Disease. Otology, Laryngology, and Rhinology; Radiology; Anæsthetics; Mental Diseases; Hygiene; Pathology; subjects other than above, at the discretion of Our Army Council, 5s. daily.

(2) (*a*) Officer in charge of a hospital.—If the number of equipped beds, as certified by the Deputy Director of Medical Services, exceeds—

50 beds	.. 2*s.* 6*d.* daily.	300 beds ..	7*s.* 6*d.* daily.
150 "	.. 5*s.* 0*d.* "	500 " ..	10*s.* 0*d.* "

Officer in charge of a medical or surgical division of a general hospital with not less than 300 beds—half the above rates.

	Daily. *s.*	*d.*
(*b*) Senior medical officer, Royal Arsenal, not exceeding	10	0
(*c*) Officer in command of the depôt, Royal Army Medical Corps	5	0
(*d*) The senior officer of the Army Medical Services with an army in the field: A rate to be fixed by the Army Council according to the magnitude of the charge.		
(*e*) The officer, if under the substantive rank of colonel, holding the appointment of senior medical officer in a command abroad, or of assistant director of medical services, if the number of soldiers is 1500 or upwards	5	0
(*f*) Adjutant R.A.M.C. Depôt	5	0
(*g*) Adjutant R.A.M.C. (Territorial Army)	2	6

Retirement and Retired Pay.

The following are the rates of pension and retired pay:—

1. Retired pay will consist of two parts: (*a*) a service element based on the officer's total service; (*b*) a rank element for the rank from which the officer retires. An officer with less than 20 complete years' service will not be eligible for retired pay.

2. The scale will be as follows, subject to the reduction of 6 per cent. referred to below:—

(*a*) Service element.—£15 a year for each completed year of service as a medical officer.

(*b*) Rank element.—

Rank from which retired.	After completing 1 year's service in the rank.	After completing each additional year's service.	Maximum rank element.
	£	£	£
Major	12	12	120
Lieutenant - Colonel	150	30	240
Colonel	290	50	390
Major-General ..	440	50	540
Lieutenant - General	590	50	690

The retired pay of an officer retiring with less than one complete year's service in the rank from which he retires will be assessed as though he had retired from the rank below.

Maximum rates of retired pay (*a*) and (*b*) together:—

	£		£
Captain and Subaltern ..	300	Colonel	800
Major	450	Major-General ..	1000
Lieutenant-Colonel ..	600	Lieutenant-General	1200

The above rates are those laid down in the Pay Warrant. They have been reduced by approximately 6 per cent. as from July 1st, 1927, and are subject to future variation with fluctuation in the cost of living.

3. Officers with seven and less than 20 years' service as medical officers may be permitted to retire with a gratuity in accordance with the following scale:—

After 7 years' service as a medical officer.. ..	£1000
" 15 " " " ..	£2800
" 18 " " " ..	£3500

THE ARMY DENTAL CORPS.

The Corps is administered by the Director-General, Army Medical Services. It is a joint service for the Army and Royal Air Force, and personnel is required to serve under either force and be interchangeable. Officers and other ranks posted for duty with the Royal Air Force will perform their duties under the Regulations of the Royal Air Force for the employment of dental personnel, but the conditions in the following tables apply equally in either force. Promotion is carried out on one general list. Regulations for admission to the Army Dental Corps should be obtained from the Under-Secretary of State, War Office, and carefully studied.

OFFICERS: *Appointment and Promotion.*

1. Commissions as Lieutenants in the Army Dental Corps may be given to persons duly qualified under regulations approved by the Army Council.

2. An officer shall be eligible for promotion to the rank of Captain on completion of three and a half years' service and to the rank of Major on completion of 12 years' service in the Corps, provided he has previously qualified in such manner as may be prescribed by the Army Council.

3. Promotion to the rank of Lieutenant-Colonel and Colonel to fill the establishments laid down from time to time for those ranks shall be made by selection of the Army Council, provided the officer has previously qualified for promotion to those ranks in such manner as may be prescribed by the Army Council.

4. Appointments are in the rank of Lieutenant, except in cases where service of three and a half years or more has been given as a temporary dental officer, when the rank of Captain will be given. Service as a temporary dental officer will count towards the three and a half years for promotion to captain, and the 12 years for promotion to Major.

Pay.

The following are the rates for officers of the Army Dental Corps:—

	Per diem. £	*s.*	*d.*
Lieutenant	0	18	10
Captain	1	3	6
Captain (after 8 years' total service	1	6	1
Captain " 10 " " "	1	8	2
Major	1	12	10
Major, after 15 years' total service	1	17	5
" " 18 " " "	2	0	0
" " 20 " " "	2	4	8
Lieutenant-Colonel	2	11	8
Lieutenant-Colonel after 3 years' service as such	2	16	4
Colonel	3	3	6

These rates are 6 per cent. below those shown in the Pay Warrant, 1926, as amended by Army Order 106/26.

The latter are subject to revision to an extent not exceeding 20 per cent., according to variation in the cost of living. The next revision takes place on July 1st, 1930.

Charge Pay.

The officer in charge of the Dental Laboratories, Aldershot, receives charge pay at the rate of 5s. a day if holding the rank of Captain, or 2s. 6d. a day if holding the rank of Major.

Allowances.

The allowances for officers of the Army Dental Corps are at the same rates as for officers of the Royal Army Medical Corps.

Retirement and Retired Pay or Gratuity.

(1) The rates of retired pay will be the same as for officers of the Royal Army Medical Corps.

(2) Voluntary retirement on retired pay will not be allowed until after twenty years' service.

(3) Earlier retirement on gratuity may be allowed :—

After 8½ years'	service as a Dental Officer,	gratuity of £1000.
,, 15 ,,		,, £2000.
,, 18 ,,		,, £3000.

The aim of the Corps is the prevention of wastage of man power on account of dental disease or dental deficiency, and, to enable this to be carried out, every recruit is inspected by a dental officer immediately after joining and all necessary treatment carried out. The soldier is re-inspected at least once a year and his dental efficiency maintained at the best standard possible. As recruits are not now enlisted unless they have sufficient natural teeth to enable them to masticate efficiently, it is hoped that the conservative nature of the treatment they will receive will reduce considerably the percentage of artificial dentures required.

INDIAN MEDICAL SERVICE.

It is the view of many senior officers in the Service that the period of depression is now passing and that the prospect is again bright for those who are fitted in physique and disposition for a medical career in India. The offer of permanent commissions on specially favourable terms to a small number of medical men of European descent who were free to sail forthwith to India met last year with the desired response, and the number of commissions granted during the last twelve months is 16.

But the new outlook involves frank acceptance of the Indian reform scheme, the essential of which is increasing participation of Indian-born subjects in the government of the country, although, so long as Europeans are employed in the various departments of the Indian Civil Service, nothing is more certain than that there will and must remain European doctors to attend them. India definitely requires European assistance, not only for the care of the military and civil European population, but for the maintenance in the country of that spirit of modern medicine which has accomplished already such mighty things, and which day by day is spreading in influence and value.

The Government of India issued a communiqué early this year dealing in detail with the reorganisation of the medical services in India. The scheme now sanctioned is based on proposals framed in consultation with local governments. The Indian Medical Service, constituted on the same broad lines as at present, will be retained primarily to meet the needs of the Indian army, and in order to maintain two essential requisites —namely, (1) the necessary minimum war reserve of medical officers, and (2) the provision for European medical attendance on officers and their families. Local governments in India will be required to employ a stated number of I.M.S. officers. It has been calculated that the war reserve to be employed by the civil side should consist of 131 British and 66 Indian officers, the larger proportion of British officers being due to the fact that they cannot be recruited on emergency in India from the ranks of private practitioners. Medical attendance on British personnel, and the requirements of civil administration, for which the Central Government is still responsible, involve the provision of a number of employments termed "residuary," the incumbents of which must be retained permanently in civil employment, so as to ensure the continuance under any circumstances of a skeleton staff to cope with civil requirements. The total number of officers required for civil employment in the I.M.S. is now calculated at 302, allotted as follows: war reserve, 200; residuary posts in provinces, 46; foreign and political departments, 17; gaols, 8; special posts under the Government of India, 14; port health officers at Bombay and Aden, 2; reserve of 5 per cent. as allowance for illness, 15. Of this total 212 will be European and 90 Indian. To provide employment for these 302 officers, 237 posts are required, 59 of which will be available under the Government of India, and 178 (of which 112 must be held by British officers) will be provided in the provinces. The estimate of the medical requirements of European medical attendance is based on data which will change from year to year as the proportion of European to Indian civil officers diminishes; it will therefore be subject to scrutiny and revision. The remaining 66 posts will be open either to Europeans or Indians, while 28 out of 59 appointments under the Government of India will similarly be open to officers of either race.

Rules forming an integral part of the reorganisation scheme have been drawn up to safeguard the varied interests of the Indian army, the provincial governments, and the medical officers themselves (vide THE LANCET, May 19th, 1928, p. 1028).

Thus the social effect of Indianisation should not press hardly on the medical service for the reason that European doctors will be chiefly requisitioned in stations with considerable European communities. In these communities the equipment and organisation of hospitals has been steadily improving and men with professional ambition will find positions which will satisfy their aspirations. On the military side the station hospital system has rendered the position of medical officers more independent by making team-work possible and permitting of specialisation in various departments of medicine and surgery. Lastly, those who join now will have unequalled prospect of advancement in a Service which has been so depleted for 10 or 15 years or more, and the terms of service announced by the Secretary of State for India in 1926 assure conditions of pay, pension, and furlough much superior to those previously offered.

The New Regulations.

Competitive examination remains suspended for the present and admission to the Service is on written application to the India Office. As sound bodily health is a first essential candidates may, if they wish it, undergo a preliminary examination by a Medical Board which meets weekly at the India Office.

Candidates must be under 32 years of age at the time of application, and must possess a qualification registered in Great Britain and Northern Ireland, under the Medical Acts in force at the time of appointment. Arising out of the recommendations of the Lee Commission the Secretary of State for India in Council after consultation with the Government of India has decided that the Indian Medical Service constituted on the same broad lines as in the past shall be retained primarily to meet the needs of the Indian Army. In order to maintain the necessary minimum war reserve of military medical officers, and to provide for European medical attendance for European officers of the Superior Civil Services and their families, local governments will be required to employ a stated number of Indian Medical Service officers. The Government of India will draw on the same Service to meet the requirements of the civil administration for which they are responsible. For the present 237 such posts have been reserved, and including the leave reserve will provide employment for 302 officers. 212 of these officers will be British medical men and 90 Indians. As the proportion of European to Indian civil officers diminishes these figures will be subject to periodical scrutiny, and, if necessary, to revision. It will be a definite condition of service for all future entrants to the Service that they will be liable to serve on either the civil or the military side. All officers are required to perform two years' military duty subsequent to permanent appointment before they can be considered eligible for civil employment. Executive medical officers in both civil and military employment may attend persons unconnected with Government service provided their duty admits of it. On the military side, however, the opportunities for private practice are not great. Service during the war as a medical or combatant officer, or in a position usually filled by an officer, counts towards promotion and pension so long as the rights of officers who have entered by competition are not interfered with.

Rates of Pay.

The monthly rates of pay for European officers of non-Asiatic domicile in the Service are as tabulated below. The rupee, it may be remembered, has now been definitely stabilised at 1*s.* 6*d.*

Rank and service in rank.	Basic pay.	Overseas pay.	Year of total service.
	Rs.	Rs.	
Lieut.	500	150	First
		150	Second
		150	Third
Captain :—			
1. During first three years' service as Captain.	650	150	Fourth
		£15	Fifth
		£15	Sixth
2. With more than three and less than six years' service as Captain.	750	£25	Seventh
		£25	Eighth
		£25	Ninth
3. With more than six years' service as Captain.	850	£25	Tenth
		£25	Eleventh
		£30	Twelfth
Major :—			
1. During first three years' service as Major	950	£30	Thirteenth and over.
2. With more than three and less than six years' service as Major	1100		
3. With more than six years' service as Major.	1250		
Lieut.-Colonel :—			
1. Until completion of 23 years' total service	1500		
2. During twenty-fourth and twenty-fifth years' total service	1600		
3. After completion of 25 years' total service	1700		
4. When selected for increased pay ..	1850		

Note.—Until the completion of 23 years' total service basic pay is regulated according to rank and service in rank (column 1) which, owing to the system of accelerated promotion, may be in advance of the time-scale of promotion. Overseas pay is regulated solely with reference to length of total service (column 4). In addition to the above rates various allowances are admissible for a large number of special appointments on both the military and the civil side which may be held by members of the I.M.S. Special high rates of pay are also attached to the numerous administrative appointments open to officers in both branches of the Service. The appointment of Director-General, I.M.S., which is held by an I.M.S. officer, carries pay of Rs.3500 per mensem. The appointment of Director of Medical Services in India, carrying pay at Rs.3200 per mensem, may also be held by an officer of the Indian Medical Service.

Initial rates of pay are based on the assumption that the majority of newly appointed officers will be bachelors. An officer, when junior, is liable to more frequent changes of station than later on in his service, and he may therefore be put to considerable expense for transfers if he has a family. Officers who are married before joining may find difficulty in living within their pay during the first few years of their service. Officers in military employment, when in command or second-in-command of the larger station hospitals, receive special allowances. On the civil side there are public health, bacteriological, research, and professorial appointments carrying special enhanced rates. Officers on appointment receive an outfit allowance of £50.

Pensions and Allowances.

The rates of pensions are as shown in the table below.

Service.	Rates per annum.	Service.	Rates per annum.
After 17 years ..	£400	After 23 years ..	£620
,, 18 ,, ..	430	,, 24 ,, ..	660
,, 19 ,, ..	460	,, 25 ,, ..	700
,, 20 ,, ..	500	,, 26 ,, ..	750
,, 21 ,, ..	540	,, 27 ,, ..	800
,, 22 ,, ..	580		

Note.—The above rates are subject to revision triennially upwards or downwards, to an extent not exceeding 20 per cent. in all, on account of a rise or fall in the cost of living, as compared with the year 1919. A deduction of 4½ per cent. on this account has already been made. Nevertheless the full pension of a lieutenant-colonel cannot be cut below the maximum of £700 under the old rules in the case of officers who entered the service before July 1st, 1920.

There are additional pensions not subject to the above reduction ranging from £65 to £350 per annum for officers who have held high administrative appointments as colonels or major-generals.

Officers on appointment are provided with free passage to India, normally by transport. The wives and families of officers who are married prior to the date of the officers' embarkation on first appointment will also be given free passage to India. Officers are granted a certain number of return passages home at Government expense during their career. There are special allowances for officers whilst on study leave.

Further particulars can be obtained on application to the Secretary, Military Department, India Office, Whitehall, London, S.W. 1. Letters should be marked "Recruitment for I.M.S."

ROYAL AIR FORCE MEDICAL SERVICE.

THE Air Council attach great importance to attracting into the Service the best type of medical man, since on the capacity of the Medical Service depends in a peculiar degree the safety and efficiency of the Air Force. The duties of a medical officer in the Air Force include not only the prevention and treatment of those ordinary diseases to which the personnel of any fighting service are liable, but the special study of the mental and physical stresses imposed on the airman in diverse circumstances and climates—a new branch of medicine which still provides considerable scope for research.

As promotion to the higher ranks of the Service is by selection from officers who are eligible by reason of length of service, and as a certain proportion of the higher ranks will be reserved for purely scientific as opposed to administrative appointments, it will be seen that there are excellent prospects for the young medical officer who exhibits ability and energy in scientific research, as well as for those who develop talents for administration.

The work to be done, therefore, has a high professional interest which, combined with good rates of pay and allowances, offers a career for medical men which should prove both attractive and interesting. The life is one which is certain to appeal to the man of wide outlook who desires opportunities for travel, sport, and games, and can find interest and enjoyment in aviation.

His duties will, as a matter of course, give him flying experience as a passenger, which is necessary for the proper study of the medical problems of aviation and for gaining first-hand knowledge of the conditions under which his comrades serve.

The establishment will consist partly of permanent and partly of short-service officers.

An officer will on first entry be granted a short-service commission for a period of three years on the active list (which may be extended to five years at the discretion of the Air Council if the officer so wishes on the recommendation of the Director of Medical Services) and of four years in the Reserve of Air Force Officers. Selections for permanent commissions will be made from officers holding short-service commissions, and those who are not selected will be transferred to the Reserve at the expiration of their period of service on the active list.

For those entrants who desire it the prospect of obtaining a permanent commission is approximately an even one. Experience has so far shown that the officers selected have included the great majority of those desirous of, and suitable for, retention in the Service; owing to the fact that the short-service commission with its gratuity after three or five years is in itself an attraction to many entrants who desire to enlarge their experience and outlook from the point of view of subsequently entering private practice, or who, on entry, have not made up their minds to the adoption of a permanent career in the Service and subsequently find that they would prefer to return to civil life.

ROYAL AIR FORCE MEDICAL BRANCH: RATES OF PAY AND ALLOWANCES.

* Except for periods of service under Indian administration. For such periods officers receive pay and allowances at rates and subject to conditions authorised from time to time by the Government of India.

† These allowances are issued only when accommodation, fuel and light, rations, and personal attendance are not available in kind. Normally, provision in kind is available for junior officers. "Married" rates of allowances are payable only to married officers who have reached the age of 30 or the rank of Squadron Leader. A colonial allowance is granted in certain commands abroad. The rates and general scheme of allowances are liable to revision as circumstances may require.

For certain purposes medical officers may be allowed to count as service their time spent in resident appointments in civil hospitals under certain well-defined and generous conditions.

Officers who have been selected for permanent commissions may be permitted to attend for a period not exceeding nine months a post-graduate course in general medicine and surgery, tropical and preventive medicine, and other special subjects. Such permission may be granted at any time when the exigencies of the Service permit during the first 10 years of service, and when attending these courses officers will receive full pay and allowances.

New entrants into the Royal Air Force Medical Service will be commissioned as Flying Officers (Medical) and will be eligible for promotion to the rank of Flight Lieutenant (Medical) after two years' service. Officers selected for permanent commissions will normally be promoted to the rank of Squadron Leader after ten years' total service. Accelerated promotion may be granted in a limited number of cases to officers who show exceptional ability after the completion of eight years' service. Promotion within establishment to the rank of Wing Commander will be by selection at any period after 16 years' total service, and that of Group Captain by selection at any period after 22 years' service.

Certain posts in these ranks are reserved for officers fully employed in professional work, such as surgery, pathology, ophthalmology, &c., numbering at present six in all. The number of these posts will be limited only by the needs of the Service and by the necessity of observing a similar proportion between the number of reserved posts and the officers from whom they can be filled, as exists between the total number of higher ranks and the remainder of the medical service. Selections for these reserved posts will be made only from officers professionally qualified to hold them. Officers filling the reserved posts will be eligible for selection to the administrative appointments of their rank, and to the highest administrative appointments.

There will be no competitive examination on entry; candidates must be under 28 years of age, be British subjects, the sons of British subjects, and of pure European descent, be nominated by the dean of a recognised medical school or teaching hospital, and will be interviewed personally by the Director of Medical Services, Royal Air Force, before acceptance. Each candidate must produce:—

1. Birth certificate. 2. Medical registration certificate. 3. A declaration containing the following information: (*a*) Age and place of birth. (*b*) That he is a British subject, the son of British subjects, and of pure European descent. (*c*) That he is ready to engage for general service at home or abroad as required. (*d*) The qualifications he is possessed of, and what medical or other appointments he has held (if any). (*e*) That he is willing to fly as a passenger whenever called upon to do so.

Each candidate will be required, before acceptance, to pass a medical examination to ensure that he labours under no constitutional or mental disease or diseases or weakness, nor any imperfection or disability which may interfere with the efficient discharge of the duties of a medical officer in any climate, in peace or war.

On appointment entrants will undergo an initial course of eight weeks, during which they will be given instruction in the special medical aspects of aviation, the organisation and administration of the Royal Air Force, and the general and special duties to be performed by officers in the Medical Branch.

In order to avoid the necessity for further examinations the position of entrants in order of seniority in the Air Force List will be determined at the end of the initial course by a system of marking and reports on the actual work done during their instruction.

Uniform and Equipment.

Medical officers are required to provide themselves with the uniform, service dress, and mess dress of their rank and with the distinguishing badges of the Royal Air Force Medical Branch. The provision of full dress is entirely optional at present. An allowance of £50 towards the cost of uniform is made on joining to candidates who have not had previous commissioned service in H.M. Forces.

Emoluments.

The emoluments of medical officers of the Royal Air Force are given in outline above. The standard rates of pay and retired pay were drawn up on the basis of the high cost of living in 1919, and 20 per cent. of each of the standard rates is detachable and subject to alteration either upwards or downwards as the cost of living rises or falls. Under this provision the current rates now in force represent a reduction of approximately 6 per cent. on the standard rates. The next revision will take effect from July 1st, 1930, and subsequent revisions will be made at intervals of three years.

RETIRED PAY.

The minimum period of service qualifying for retirement on retired pay is 20 years. Standard rates of retired pay are as follows:—

Air Officers.

Air Vice-Marshal ..	.. £790 to £1010 per annum.
Air Commodore ..	.. £650 ,, £950 ,, ,,

The maximum standard rates of retired pay and the compulsory retiring ages for the several ranks are:—

Rank.	Yearly rate of retired pay.	Compulsory retiring age.
	£	
Air Vice-Marshal ..	1010	60
Air Commodore ..	950	57
Group Captain.. ..	900	55
Wing Commander ..	600	51
Squadron Leader ..	500	48

Retired Pay of Officers below Air Rank.

Age on retire-ment.	Standard yearly rate of retired pay.	Years of service.	Addition for each extra year of service.*	Deduction for each deficient year of service.*
	£		£	£
40	300	17	15	15
41	337	17	15	15
42	375	18	15	15
43	412	18	15	15
44	450	19	15	15
45	487	19	15	15
46	525	20	15	15
47	562	20	15	15
48	600	21	15	15
49	637	21	15	15
50	675	22	15	15
51	697	22	22	15
52	720	23	22	15
53	742	23	22	15
54	765	24	22	15
55	790	24	22	15

* Limited to five years.

Gratuities.—A permanent officer allowed to retire before having qualified for retired pay may be granted a gratuity provided he has not less than ten years' commissioned service, namely:—

£1500 if he has 10 but less than 15 years' commissioned service.
£2500 ,, 15 or more than 15 ,, ,, ,,

Short-service officers will be eligible on passing to the Reserve for gratuities on the following scale: £100 for each of the first two complete years of service, £150 for each of the third and fourth complete years, and £200 for the fifth complete year; that is:—

For three years' service on the active list .. £350
For five ,, ,, ,, ,, .. £700

These gratuities will not be payable to officers granted permanent commissions, but their service on a short-service commission will count towards retired pay.

COLONIAL MEDICAL SERVICE.

IN the self-governing Dominions (Canada, Australia, New Zealand, the Union of South Africa, and Newfoundland), and territories under their control, such as Papua and the Cook Islands and in the self-governing colony of Southern Rhodesia, medical appointments are made concerning which information can be obtained from the High Commissioners or Agents-General in London; in North Borneo application should be made to the British North Borneo Company, 17, St. Helen's-place, E.C., for appointments; and those in Sarawak are in the hands of H.H. the Rajah. Much valuable information will be found in the "Professional Handbook," Part II., issued by the Oversea Settlement Office, Caxton House, Tothill-street, London, S.W. 1, price 9*d*.

As a general rule, each Colony or Protectorate has its own public service distinct from that of every other; and it is usually only the higher officers who are transferred by the Secretary of State from one Colony to another. There are three exceptions to this rule: (*a*) The West African Medical Staff, which serves Nigeria, the Gold Coast, Sierra Leone, and the Gambia, is one service. (*b*) The East African Medical Service, which serves Kenya, Uganda, Zanzibar, Nyasaland, Somaliland, and the Tanganyika Territory is one service. (*c*) In practice the medical services of the Straits Settlements and the Malay States may be regarded as one, as the officers may be and frequently are transferred from the Colony to the States or vice versa; the two services are now called the Malayan Medical Service.

The Colonies, Protectorates, and Mandated Territories to which medical officers are appointed by the Secretary of State for the Colonies are (*a*) the West African—viz., Nigeria, the Gold Coast, Sierra Leone, and the Gambia, with the Mandated Territories of Togoland and the Cameroons; (*b*) the East African—viz., the Kenya Colony and Protectorate, Uganda, Nyasaland, Somaliland, and Zanzibar Protectorates, the Tanganyika Territory, and Northern Rhodesia; (*c*) the Eastern—viz., Ceylon, the Straits Settlements and Malay States, Hong-Kong, Mauritius, and Seychelles; (*d*) the West Indian—viz., Jamaica, Trinidad, the Windward Islands, the Leeward Islands, Barbados, and the Bahamas; (*e*) Fiji and the Western Pacific, Cyprus, Gibraltar, St. Helena, British Guiana, British Honduras, Bermuda, and the Falkland Islands; and (*f*) Palestine.

In Ceylon, Mauritius, Jamaica, Barbados, the Bahamas, and Bermuda vacancies are practically always filled locally by the appointment of qualified native candidates, or—in the case of some of the higher posts—by transfer from other Colonies. In the Bechuanaland Protectorate, Basutoland, and Swaziland appointments are usually filled locally. Appointments in Malta are all filled locally. In addition, certain medical appointments in the service of the Government of Iraq are filled with the concurrence, and normally upon the recommendation, of the Secretary of State. Vacancies occur most regularly and frequently in the West African Medical Staff, the East African Medical Service, and the Straits Settlements and Malay States.

All applicants for medical appointments in the gift of the Secretary of State for the Colonies should be under 35 years of age, and must be doubly qualified; preference will be given to those who have held hospital appointments as house physicians and house surgeons; testimonials to character and professional competence will be required, and every officer before being definitely appointed will be medically examined by one of the consulting physicians of the Colonial Office: Sir William Prout, C.M.G., O.B.E., and Dr. A. E. Horn, C.M.G., 104, Harley-street, London, W. 1; Major-General J. J. Gerrard, C.B., C.M.G., the Royal Hospital, Kingsbridge, Dublin; Dr. Foster Coates, 22, College-gardens, Belfast; and Lieut.-Colonel Glen Liston, C.I.E., I.M.S., 33, Comely Bank, Edinburgh, and Dr. C. V. Le Fanu, 33, Rodney-street, Liverpool. Applications for such appointments must be addressed to the Private Secretary (Appointments), Colonial Office, 2, Richmond-terrace, Whitehall, S.W. 1.

EAST AFRICAN MEDICAL SERVICE.

The Medical staffs of the Kenya Colony and Protectorate, the Uganda, Nyasaland, Somaliland, and Zanzibar Protectorates, and the Tanganyika Territory form one service, the members of which are liable to be posted or transferred to any of the Dependencies as the exigencies of the service may require. The preferences of individual officers are, however, taken into consideration as far as possible.

Selected candidates are appointed as medical officers on probation in the first instance for two years, at the end of which period their appointments are made permanent if their service has been satisfactory. Unless the Secretary of State directs to the contrary, they are required to attend a course of instruction at the London or Liverpool School of Tropical Medicine or the University of Edinburgh before taking up their appointments. If such a course is not taken before proceeding to East Africa, they are required to take it during their first leave of absence. Medical officers (but not sanitation officers) are permitted to take private practice at some stations on the understanding that they give precedence to their official duties. It must be understood that additions to their income from this source are not likely to be substantial, and that the privilege is liable to withdrawal at any time.

Officers are provided with quarters free of rent or the Government may provide temporary accommodation, or an allowance in lieu of quarters may be paid. The salary of a medical or sanitation officer is £600 per annum, rising by annual increment of £30 to £810, and thence by increments of £40 to £920, subject to an efficiency bar at £840. Senior medical officers and senior sanitation officers are paid on the scale £1000 by annual increments of £50 to £1100. Officers who possess the Diploma in Public Health on entering, or who acquire it while in the Service, receive two special increments in the scale.

Officers of the East African Medical Service are permitted to retire with gratuity, if they wish, instead of waiting to retire on pension as follows: (*a*) After nine years' service, of which at least six must have been spent in East Africa, £1000; (*b*) after 12 years' service, of which at least eight must have been spent in East Africa, £1250. If an officer elects to retire with gratuity he thereby forgoes all claim to pension.

The grades and salaries (apart from ordinary medical and sanitation officers) in the medical departments are as follows:—

Kenya.—Director of Medical and Sanitary Services, £1500; Deputy Director of Medical Service, £1200: Deputy Director of Sanitary Service, £1200; Deputy Director of Laboratory Service, £1200.

Uganda.—As Kenya.

Tanganyika Territory.—As Kenya.

Nyasaland.—Director of Medical and Sanitary Services, £1200; Medical Entomologist, £1000–£50–£1100.

Zanzibar.—Director of Medical and Sanitary Services, £1100; Deputy Director of Sanitary Service, £1200: Resident Surgical Officer, £1000–£50–£1100.

Somaliland.—Principal Medical Officer, £1000–£50–£1100.

There are also the following posts:— Resident Surgical Officers (Kenya and Uganda), £1200; Specialist Officer, Sleeping Sickness (Uganda), £1150; Medical Superintendent and Principal of Medical School, Mulago Hospital (Uganda), £1150; Sleeping Sickness Officer (Tanganyika Territory), £1000–£50–£1100; Senior Bacteriologists (Kenya and Uganda), £1000–£50–£1100.

Sanitation officers are selected from the ranks of medical officers as occasion arises.

ASIA.

Straits Settlements and Federated Malay States.—European medical officers are appointed on the following scale of salaries: $500 per mensem, rising to $550 per mensem during three years' probation; then, if they are placed on the pensionable establishment, rising to $575 per mensem, and thence by annual increments of $25 per mensem to $800 per mensem, with a strict efficiency bar at $600 per mensem. Officers possessing the D.P.H. receive an additional allowance (non-pensionable) of $100 per mensem.

Above the concluding figure of $800 *per mensem* there are certain higher appointments, as follows: *Principal Civil Medical Officer, Straits Settlements*, and Principal Medical Officer, Federated Malay States, $1200 *per mensem*; *Director, Institute for Medical* Research, Federated Malay States, Chief Health Officer, Federated Malay States, and Principal Medical College, Straits Settlements, $1100 per mensem; Senior Surgeon, Singapore, $1050 per mensem; 3 Chief Surgeons, Federated Malay States, $1000 per mensem; Medical Officer and Ophthalmic Surgeon, $1000 per mensem; 6 posts at $1050 per mensem; and 17 posts at $850 per mensem, rising annually by $30 to $1000 per mensem. There are also 14 medical appointments, including several senior posts, in the Unfederated Malay States.

The following temporary allowances are at present paid to all officers recruited from Europe in the Government Services of the Straits Settlements and Federated Malay States: unmarried officers, 10 per cent. of salary; married officers, 20 per cent. of salary. Private practice by Government medical officers is not allowed, but consultation work with another practitioner is permitted. Information about general conditions in Malaya is obtainable from the Malay States Information Agency, 57, Charing Cross, S.W. 1.

Seychelles.—The chief medical officer receives Rs.7000 per annum. There are four assistant Government medical officers, two receiving Rs.6500, the others Rs.3000 per annum.

Hong-Kong.—The present establishment of the medical department is: director of medical and sanitary services, £1200–£50–£1450; deputy director, £1125–£25–£1200: senior medical officer, £1025–£25–£1100; three medical officers of health, £740–£30–£1040; health officer of the port. and second health officer of the port, £740–£30–£1040; five medical officers, £600–£30–£1020; bacteriologist, £800–£1100; assistant bacteriologist, £740–£30–£1040; radiologist. £740–£30–£1040; analyst, £625–£25–£900; assistant analyst, £400–£25–£700. A temporary allowance on a scale varying with the sterling exchange value of the dollar is at present payable. Salaries are converted locally at the rate of 2*s.* = $1. Free quarters are not provided, but in certain instances a rent allowance is paid by the Government.

AMERICA.

British Guiana.—There are the following posts in the medical service of the Colony: one surgeon-general, £1000–£1200 per annum, with consulting practice: one medical officer of health, £900; ophthalmologist, £700; one bacteriologist and pathologist, £700; 37 medical officers at £500–£25–£700. Most of the senior posts in institutions carry duty allowances (varying from £50 to £300 per annum) and quarters.

Trinidad and Tobago.—In Trinidad and Tobago there are about 40 appointments. Government medical officers receive salary at the rate of £100 per annum, rising by annual increments of £25 to £600. An officer appointed to a district receives, in addition to his salary, a travelling allowance varying from £100 per annum in a normal district to £150 per annum, and is allowed private practice, the value of which is estimated at from £50 to £800 per annum. Officers employed in institution work receive a duty allowance varying from £50 to £300. Medical officers having completed 10 years' resident service are pensionable at the age of 55.

Windward Islands (Grenada, St. Lucia, St. Vincent). There are over 25 appointments. The chief medical officer, Grenada, receives £750. The chief medical officer, St. Lucia, receives £600–£700 plus forage and subsistence allowances; the post is pensionable, but private practice is not allowed except as a consultant. Most of the remaining appointments are district appointments with the right to private practice attached; the salaries paid by Government are on the scale from £400–£500, except in St. Vincent, where the maximum is £450. The Governor has the power to transfer a medical officer from one island to another. Appointments are pensionable.

Leeward Islands (Antigua, St. Christopher and Nevis, Dominica, Montserrat, Virgin Islands).—The appointments are similar in number and character to those in the Windward Islands, and are pensionable. An officer when first sent out is not appointed to a particular island but to the service of the Leeward Islands, with a salary of £350, and is later appointed to a definite district at a salary varying from £312 to £400–£25–£450, and the Governor decides as to the district which is to be allotted to him, according to station. He is liable to be transferred at the Governor's discretion to any medical district in the Leeward Islands. The medical officers, except in St. Christopher and Nevis, receive fees for successful vaccinations, post-mortem examinations, evidence at courts of justice, certificates of lunacy, and, in the larger islands, for burial certificates. They are also, as a rule, allowed private practice. The chief medical officer, St. Christopher and Nevis, receives £700–£25–£750, but is not allowed private practice, except as a consultant.

British Honduras.—There are seven medical appointments (besides the post of principal medical officer) at a salary of $2430 per annum with increments of $120 to $3150. Unless they already possess a diploma of public health, medical officers are liable to be required, before they join the colony, to undergo a course of instruction at a laboratory of public health or analogous institution. The value of the dollar is the same as that of the United States dollar.

OTHER OVERSEAS APPOINTMENTS.

Fiji.—The Chief Medical Officer receives £1000–£50–£1100, with free quarters, unfurnished; the Medical Superintendent, Colonial War Memorial Hospital, £800–£50–£1000, with £40 car allowance and free quarters; the Medical Superintendent, Leper Asylum, £750–£50–£950, with completely furnished quarters and one servant; the Medical Officer of Health, £750–£25–£900, no quarters provided. There are 14 District Medical Officers who receive £500–£25–£725, with partly furnished quarters or £50 house allowance (at the option of the Government) and duty allowance of £50 per annum in districts where no private practice exists. In certain districts house allowances or car allowances are granted. In others a medical officer is provided with a launch or boat. District Medical Officers are allowed private practice on the understanding that their official duties are not neglected. In five districts the Medical Officer is also District Commissioner and receives an additional allowance of from £175 to £275 and free partly-furnished quarters. In most districts there is private practice, the value of which has been estimated at from £100 to £600 a year.

Western Pacific High Commission.—The staff in the British Solomon Islands Protectorate consists of a Senior Medical Officer (£650–£750), two District Medical Officers (£550–£650), and one Travelling Medical Officer (£550–£650). Partly-furnished quarters are provided and a local allowance of £50 per annum is paid to the Senior Medical Officer and the District Medical Officers. A local allowance of £50, consolidated travelling and subsistence allowance £200, and partly-furnished quarters are provided for the Travelling Medical Officer.

In the Gilbert and Ellice Islands Colony there is a Senior Medical Officer (£650–£750), with partly-furnished quarters, and one Medical Officer (£600–£25–£650), with partly-furnished quarters or house allowance. There is hardly any private practice in the British Solomon Islands Protectorate or the Gilbert and Ellice Islands Colony.

Cyprus.—There is a chief medical officer paid at the rate of £750, rising by annual increments of £25 to £850, and three district medical officers paid at the rate of £500 a year, rising by annual increments of £20 to £600 a year, all enjoying private practice (except the chief medical officer and one of the district medical officers, who are allowed consulting practice only). There is also a post of consulting surgeon, £400–£20–£600 a year, with consulting practice. There is also a medical officer of health on £600, rising by £20 increments to £750 without private practice, and a specialist in venereal diseases with a salary of £700 a year and consulting practice; these are the only medical appointments open to British candidates.

Gibraltar.—There is a surgeon of the Colonial Hospital receiving £730, and private practice. There are also two assistant surgeons with a salary of £600 for 3 years and thereafter £650–£25–£700 per annum, who are allowed private consulting practice only. Free quarters, unfurnished, are provided for all three officers.

St. Helena.—The colonial surgeon at present receives £550 per annum, fees estimated at about £27 a year, and £30 horse allowance. The assistant colonial surgeon at present receives £500 a year and £30 horse allowance. Private practice is allowed, and such practice, together with the duties of non-Government appointments, is divided between the colonial surgeon and the assistant colonial surgeon in a proportion approved by the Governor. The value of private practice and appointments is estimated at about £536 a year.

Falkland Islands.—There are two appointments. The colonial surgeon is paid at the rate of £600 per annum, with free furnished quarters. The assistant colonial surgeon is paid at the rate of £500 per annum, with an allowance of £50 per annum in lieu of quarters. Private practice is shared between the colonial surgeon and the assistant colonial surgeon. The office of colonial surgeon is pensionable. The medical service of this colony is now under review.

Palestine.[1]—The grades and salaries of higher appointments in the Department of Health are: Director, £P.1200, plus £P.200 expatriation allowance. Deputy Director, £P.900–50–£P.1100, plus £P.150 expatriation allowance. Assistant Director (Laboratories), Specialist Surgeon,[2] and five Senior Medical Officers, £P.750–25–950, plus £P.100 expatriation allowance. One Senior Medical Officer and Government Analyst, £P.550–25–750, plus £P.100 expatriation allowance. The remainder of the staff is recruited locally. A temporary and variable cost-of-living allowance is at present payable in addition to the salaries stated above.

Iraq.—The grades and salaries of the principal appointments in the Department of Health are: Rs.1800–100–2800 a Inspector-General of Health. month; Health Specialists, Directors of Hospitals and Institutes. Chief Medical Officers in Mosul and Kirkuk. Medical Officers of Health in Baghdad and Basra, Rs.1500–75–1800–100–2300 a month; Medical Officers. Rs.1200–75–1800 a month. Posts in the service of the Government of Iraq are not pensionable. Every officer (unless serving on a 3 years' contract) is required to contribute one-twelfth of his pay to a provident fund, to which the Government makes a contribution equal to one-sixth of his pay.

---

[1] £P.1 = £1 sterling.

[2] A certain amount of private practice is allowed.

LEAVE AND PENSIONS.

Leave and Passages.—Leave of absence in East Africa. The normal tour of service is 20 to 30 months (less in Somaliland) after which leave is granted with full salary for 2½ to 3½ days, according to the districts in which the officer has served, for each month of service, plus the period of the voyage to England. If the officer is returning to East Africa for further service, he receives a further similar amount of leave, plus the period of the voyage to East Africa. Extensions of leave with full salary are given in case of sickness or in the case of officers attending approved courses of instruction. In addition to the above, local leave may be granted up to 14 days a year. Officers serving in Northern Rhodesia are allowed four (or two) days' leave in respect of each month of service. Free first-class passages are provided for the officer on first appointment and on leave, and in certain cases assistance towards family passages is given.

In the Malay Peninsula two months' leave of absence with full salary may be granted in respect of each year's service, and this leave may be accumulated up to a maximum of eight months. Additional leave on half-pay may be granted on special grounds. Officers are provided with free passages on first appointment for themselves and their families (i.e., wife and children up to five persons, inclusive of the officer). Under temporary regulations at present in force, free return passages on leave to all officers (and their wives and their children under the age of 10) irrespective of salary.

In other Colonies outside Tropical Africa, subject to the necessities of the service, leave of absence on half salary may be granted after a period of three years' resident service without any special grounds. It may be given before the expiration of that period in case of serious indisposition, or of urgent private affairs. In the absence of special grounds, the leave must not exceed one-sixth of the officer's resident service; on special grounds it may exceed that period by six months. In addition to the above, vacation leave on full pay may be granted, if no inconvenience or expense is caused thereby, not exceeding three months[3] in any two years. British Guiana, Jamaica, and Trinidad officers are allowed to accumulate full-pay leave at the rate of six weeks for each year's service up to six months, exclusive of the period of the voyages to and fro, and no leave of absence may (except in very special circumstances) exceed six months in all unless the officer has served for five years or more without leave, in which case two months on half-pay may be taken in addition to six months' full-pay leave.

On first appointment an officer will, except in the case of a few Colonies possessing Representative Assemblies, be provided by the Crown Agents for the Colonies with free passages to the Colony for himself and his wife and children, if any, not exceeding four persons besides himself. The officer so appointed will be required to execute an agreement binding him to repay the cost of the passage or passages so obtained in the event of his leaving the Government service within three years. An officer taking leave out of the Colony has in most cases to provide his own passages.

Pensions.—East Africa.—Officers on the pensionable establishment may retire (or be retired by the Government) on attaining the age of 50 years; but they may be retained in the service, with their own consent, for such further period as the Government may recommend. Earlier retirement in the event of ill-health is also provided for. Pension is computed at one-four hundred and eightieth of pensionable emoluments—i.e., salary and value of free quarters[4] in respect of each month's pensionable service—at the time of retirement, subject to an average of emoluments for the last three years before retirement instead of the actual emoluments at the time of retirement being taken as the basis for calculation in certain circumstances.

Other Colonies.—In most of the other Colonies an officer holding a pensionable appointment may be allowed in the case of ill-health to retire on a pension after ten full years' resident service; otherwise he must have attained the age of 55. For ten full years' resident service fifteen-sixtieths of the average annual salary of the retiring officer's fixed appointments for three years prior to retirement may be awarded, to which one-sixtieth may be added for each additional year's service; but no addition will be made in respect of any service beyond 35 years. For pension purposes absence on vacation leave counts as full service, and leave on half-pay as half service. In a few cases the retiring age is 60 and the pension after ten years' service is ten-sixtieths instead of fifteen. In the Straits Settlements and Malay States, an officer may, with the consent of Government, retire at age 50. Pensions are calculated on a basis of length of service in months instead of years.

WEST AFRICAN MEDICAL STAFF.

Applicants for appointment as medical officers or medical officers of health in the West African Medical Staff (the higher grades will usually be filled by promotion from the lower) must be British subjects of European parentage and between 23 and 35 years of age; preference is given to candidates who are over 25 years of age. Applicants must possess a complete double qualification, and must be on the Medical Register. Passages for wives and children are not provided by the Government; and houses for the wives of junior medical officers are rarely available. Officers are not usually allowed to take their wives and young children out with them until they have acquired experience of the local conditions and have obtained the sanction of the Governor. When an officer has obtained permission to be accompanied by his wife a grant of one-half the cost of his wife's passage to and from West Africa is made subject to certain conditions.

Candidates whom it is proposed to select for appointment will have to be medically examined by one of the medical advisers of the Colonial Office (or, in the case of those residing in a Colony, by a medical officer appointed by the Colonial Government), and no appointment will be made unless the candidate is declared to be physically fit for service in West Africa. Candidates are allowed to express a preference for any particular Colony, and their wishes in this respect will be borne in mind and met as far as possible, but they are liable to be posted in the first instance, or transferred afterwards if necessary to any other West African Colony at the discretion of the Secretary of State. Candidates who wish to be posted to Nigeria will probably find it useful to be able to ride. Transfers from one Colony to another will be made as seldom as possible. Candidates should on no account apply for, or accept, a West African appointment in the expectation of ultimately being transferred.

Those transferred to pensionable Crown appointments elsewhere than in West Africa do not forfeit their claim to pension in respect of their West African service on final retirement, provided that they have been members of the staff for at least 12 months. Every officer selected for appointment is required to have himself revaccinated before proceeding to West Africa, unless one of the medical advisers of the Colonial Office certifies that this is unnecessary.

---

[3] Or, in the case of Fiji and the Western Pacific and the Falkland Islands 4½ months in any three years.

[4] The value of free quarters for pension purposes is taken as 15 per cent. of the minimum salary of the grade in which an officer is serving at the time of retirement, subject to a maximum of £150.

Instruction in Tropical Medicine.—Every candidate selected for appointment will, unless the Secretary of State decides otherwise, be *required* to undergo a course of instruction either at the London School of Hygiene and Tropical Medicine, Endsleigh-gardens, N.W. 1, or at the Liverpool School of Tropical Medicine, Liverpool University, or at Edinburgh University. The cost of tuition will be borne by the Government, but candidates must make their own arrangements for board and lodging; an allowance of £25 a month will be paid to them monthly in arrear while they are under instruction. Payment of the allowance will be made subject to the candidate signing an agreement by which he is bound to refund it (1) if he declines to accept an appointment in any of the Colonies for which he may be selected; (2) if he fails to obtain a certificate or diploma; (3) if he relinquishes the Service for any other reason than mental or physical infirmity, or is removed for misconduct, within three years of his arrival in West Africa.

If at the end of the session there exists no vacancy in the Staff to which a candidate can be appointed, he will be placed in a Reserve and granted an allowance at the rate of £200 a year until the occurrence of a vacancy.

Leave of Absence.—European officers in West Africa may be granted vacation leave on full salary not exceeding in all one week's leave in the United Kingdom for every completed calendar month of total residential service in West Africa, plus the time necessarily taken on the journey to the United Kingdom, and, if the officer is returning to West Africa for further service, the time necessarily taken on the journey from the United Kingdom to the Colony. Vacation leave may be granted without any special grounds after 18 consecutive calendar months of residential service in West Africa. An officer will not be required to serve a tour of more than 24 consecutive calendar months' residential service except in special circumstances; and the Governor may grant vacation leave to any officer at any time after he has completed 12 consecutive calendar months' residential service within the above limits, the actual length of each officer's tour will be at the discretion of the Governor. Vacation leave on full salary may also be granted to an officer if he is invalided from West Africa after less than 12 consecutive calendar months' residential service, and sick leave on full salary may be granted for any period not exceeding six calendar months.

Appointments and Salaries.—Medical officers for the West African Colonies and Protectorates—namely, the Gambia, Sierra Leone, the Gold Coast (including Ashanti and the Northern Territories), and Nigeria (Southern and Northern Provinces)—are selected by the Secretary of State for the Colonies, and are on one list for employment and promotion. The grades and emoluments of the Staff are at present as follows:—

The Director of the Medical and Sanitary Service, Nigeria, receives a salary of £1800 a year, with a duty allowance at the rate of £360 a year. The Director of Medical and Sanitary Service in the Gold Coast receives a salary of £1600 a year, with a duty allowance at the rate of £320 a year. The Director of Medical and Sanitary Service in Sierra Leone receives a salary of £1400 a year, with a duty allowance at the rate of £280 a year. The Deputy Director of Medical and Sanitary Service, Nigeria, and the Deputy Director of Sanitary Service, Nigeria, receive salaries of £1500 a year, with duty allowances at the rate of £300 a year. The Deputy Director of Medical and Sanitary Service, Gold Coast, and the Assistant Director of Medical and Sanitary Services, Nigeria, receive salaries of £1400 a year, with duty allowances at the rate of £280 a year. Assistant Directors Medical Service: There are seven appointments on this grade, five in Nigeria, two in the Gold Coast. The salary is at the rate of £1300 a year, with duty allowance at the rate of £260 a year. The Assistant Director of Sanitary Service, Nigeria, the Deputy Director of Sanitary Service in the Gold Coast and the Deputy Director of Sanitary Service in Sierra Leone receive salary at the rate of £1300 a year, with duty allowance at the rate of £260 a year. Specialists: The number of these appointments is not fixed, officers of outstanding professional merit being *eligible* for appointment. The salary is at the rate of £1300 a year, with duty allowance at the rate of £280 a year. After five years' approved service as such, the specialist officer is eligible to receive a salary at the rate of £1400 a year, with duty allowance at the rate of £280 a year. There are at present five officers appointed specialists in Nigeria, three in the Gold Coast, and one in Sierra Leone. Senior Medical Officer: There are twenty appointments of this grade, with salary at the rate of £1000 a year, rising by annual increments of £50 to £1150 a year, and seniority allowance at the rate of £100 a year. The Senior Medical Officer, Gambia, is allowed "staff pay" of £150 a year, in addition to duty allowance, but he is debarred from private practice. Senior Sanitary Officer: *There are nine appointments of this grade, with salary at the rate of £1050* a year, rising by annual increments of £50 to £1200 *a year, and a* duty allowance at the rate of £210 a year. Possession of the *Diploma in Public Health is usually required for appointment to this* grade. Special facilities are granted to study for the diploma during leave. *Medical Officers of Health*: There are at present 24 appointments of this *grade. The* salary scale is the same as that of Medical Officers, except that Medical Officers of Health are granted an initial *salary at the* rate of £800 a year, together with seniority *allowance at the rate of* £72 *a year and staff pay* at the rate of £150 a year, half of which is payable during leave. After three years' service on the *maximum of* the scale, viz., £960 a year, and on undergoing an approved *course of* study, Medical Officers of Health are eligible, if unpromoted, *subject to the recommendation of the Governor, to be placed* on the scale £1000 a year rising by annual *increments of* £50 to £1150 a year, together with seniority allowance at the rate of £100 a year and staff pay as before. The holders of these appointments are not allowed private practice. *Candidates selected for service as Medical Officers of Health* must obtain the Diploma in Tropical Medicine and Hygiene of Cambridge, London, or Liverpool as a condition of appointment, or must be in possession of the Diploma in Public Health. They are appointed subject to the condition that, *if after a period of service in West Africa they are considered* unsuitable to serve in that capacity, they may be called upon to transfer to the medical side. In such cases the officers are given the rate of salary which they would have reached if they had been appointed to be Medical Officers instead of Medical Officers of Health in the first instance. Medical Officer: The salary attached to this grade is at the rate of £660 a year, rising by annual increments of £30 to £720 a year. Then, if confirmed in the appointment, £720 a year, rising by annual increments of £40 to £960, with seniority allowance at *the rate of £72 a year. Before passing £800, medical officers are required to take a special course of study for three months. If they obtain satisfactory certificates at the end of the course they draw their further increments up to £960 a year.*

A medical officer who has served for three years on the maximum salary of this scale (£960) without obtaining promotion is eligible, if recommended by the Governor, to be placed on the scale £1000–£50–£1150, with £100 seniority allowance (as for Senior Medical Officers).

Special Appointments.—The Director of the Medical Research Institute, Lagos, and the Director of the Medical Research Institute, Accra, receive a salary of £1300 a year, with a duty allowance of £260 a year, rising after five years' approved service to a salary at the rate of £1400 a year and duty allowance at the rate of £280 *a* year. There are a number of appointments for pathologists and bacteriologists in Nigeria and the Gold Coast. The salary and other conditions attached to these posts are similar to those of Medical Officers of Health. Duty allowances, seniority allowance, and staff pay are not pensionable emoluments.

Increments.—Increments to salaries are payable only when the service of *an officer* during the period of employment qualifying for increment is *approved.*

Payment of Salaries.—Information as to the payment of officers' salaries or of monthly remittances to persons in England may be obtained from the Crown Agents for the Colonies, 4, Millbank, S.W. 1. All allowances are paid locally.

All officers of the staff, except *directors*, deputy directors, assistant directors, senior sanitary officers, *medical officers of health*, research officers, and a *few other officers holding* special appointments, *are at present allowed to* take private practice, provided that it does not interfere with the faithful and efficient performance of their official duties, but it is within the power of the Governor to withdraw or suspend the privilege in such places and for such periods as he may consider desirable. Private practice does not exist at many stations, and no guarantee can be given that an officer will be posted to a station in which he will be able to practise privately. As a general rule, and subject to the exigencies of the service, stations where there is private practice are allocated to senior members of the Staff.

Pensions and Gratuities.—Pensions and gratuities on retirement are granted in accordance with the law and regulations of each individual Colony.

Fuller information can be obtained from the Private Secretary, Colonial Office, 2, Richmond-terrace, London, S.W.1.

SUDAN MEDICAL SERVICE.

This Service is responsible for carrying out civil, medical, and public health duties in the Sudan.

The staff consists of: (*a*) A Director, pay £1500–£2000. (*b*) A Senior Physician and a Senior Surgeon to the Khartoum and Omdurman Civil Hospitals, each with a pay of £1200–£1750. (*c*) An Assistant Director and Medical Officer of Health. Khartoum Province, pay £1200–£1750. (This latter post is temporary, and the terms and duties are subject to alteration). (*d*) 31 British "Senior Medical Inspectors" and "Medical Inspectors," whose pay commences at £720 and rises, subject to the recommendation of the Director, by five biennial increases to £1080, and after 13 years' service to £1200. The Senior Medical Inspectors are eligible, by selection, for the four senior posts. All Medical Inspectors are appointed, in the first place, on probation for two years, and if at the end of that time they are accepted for permanent service under the Sudan Government, the first increase of pay is subject to their passing an examination in Arabic.

In addition to the above there are (*e*) a number of Medical Officers trained at one of the Syrian Medical Schools, besides (*f*) Sudanese Medical Officers trained at the School of Medicine at Khartoum. There are several native (*g*) Assistant Medical Officers, who have been given a purely practical training in one of the larger hospitals in the Sudan.

Amongst the attractions of the Service are: The great variety of the work met with among many different races of the Sudan; *leave* of 90 days, which is granted every year after the first 18 months of service; *study-leave*, which may be given for some definite purpose, whilst two years towards pensionable service may be granted to those who have special qualifications and experience. The pension for Medical Inspectors who retire after 20 years' service is not less than £E.500 a year. If, however, he serves for a longer period, or is appointed to one of the higher posts, he will receive a larger pension. Private practice is allowed, but is limited to a few of the larger towns, and may be carried on so long as it does not interfere, in any way, with official duties. These duties include acting *as consultant* to the principal hospitals and the supervision of medical and public health work, the *inspection* of schools, the examination of candidates for Government service and pension, and the training of *Assistant* Medical Officers and native Sanitary Overseers. The Khartoum Medical School is staffed, mainly by members of the Medical Service, who receive an additional remuneration of £250 a year for their work as teachers. A Registrar of the Medical School is also selected from the Service, who receives £250 a year extra pay.

The country is developing rapidly, and the Medical Department is being increased to meet its growing requirements. Vacancies are always advertised in THE LANCET as they occur.

Candidates must be single and under 30 years of age, and they must have held a resident post, preferably that of house surgeon, in a large general hospital. As a rule they are required to take out a course in Tropical Medicine before they leave England for the Sudan. The fees for this course are paid by the Sudan Government, and in addition, an allowance of £4 15*s*. per week is made, under certain circumstances, to each selected candidate who attends it.

Inquiries for further information should be made to Dr. Acland, 19, Bryanston-square, London, W. 1, or to the Deans of the principal medical schools.

WOMEN'S MEDICAL SERVICE FOR INDIA.

AMONG careers open to medical women abroad the Women's Medical Service for India deserves honourable mention. This service is open to fully qualified medical women of British or Indian nationality, and with the present amount of Government subsidy the number of medical officers is limited to 44. Medical women proceeding to India to join the Women's Medical Service receive a sufficient sum for a first-class passage to India. On landing they are posted to one of the larger women's hospitals to gain Indian experience and to learn the language. During this period (from six months to two years) private practice is not allowed. For a further period they are appointed to act temporarily for medical women on furlough, during which time private practice is allowed. They are then definitely appointed to the charge of hospitals. Private practice is always allowed after the first two years, provided it does not interfere with official duties. The only exception is in administrative or educational posts, when an allowance in lieu of practice is given. The amount obtained from practice varies according to the station, but in most cases it forms a fair addition to the salary, varying from £150 to £1000 a year.

Excellent opportunities for surgery—especially gynæcological—are found in the Women's Medical Service. To those who are not keen surgeons opportunities are likely to open in the future in connexion with maternity and child welfare; medical women with administrative ability are also needed for the inspection of women's hospitals and other medical institutions.

Rates of pay are as follows:—

Years of service.	Overseas *allowance* per mensem.	Salary per mensem.	English equivalent* per annum.
1 to 3	Rs.100	Rs.450	£440
4 to 6	,,	Rs.500	£480
7 to 9	,,	Rs.550	£520
10 to 12	,,	Rs.600	£560
13 to 15	Rs.150	Rs.650	£600
16 to 18	,,	Rs.700	£640
19 to 21	,,	Rs.750	£680
22 to 24	,,	Rs.800	£720
over 24	,,	Rs.850	£760

* At rupee value 1*s*. 4*d*.

Furnished quarters are provided, *representing* an additional Rs.150 per mensem.

The cost of living in India is much higher than formerly, but it should be possible for a medical woman (with house provided) to meet actual household expenses for about Rs.200 per mensem, leaving the remainder of her salary for dress and personal expenses. To this must be added the necessary saving to meet additional expense for furlough and leave spent in the hills.

One month's privilege leave on full pay is granted each year. Furlough on half-pay at the rate of two months for every year of service is granted after every three years. Study-leave on two-thirds pay is granted to the extent of 12 months in the total service. There is a provident fund to which members of the service contribute 10 per cent. of their pay. The service contributes another 10 per cent., which accumulates at interest and is repaid on retirement.

Admission to the service is made by selection. Candidates in the United Kingdom should apply to the Hon. Secretary, United Kingdom Branch of the Countess of Dufferin's Fund, care of Major-General J. B. Smith, India Office, Whitehall, London.

Instruction in Tropical Medicine.—Every candidate selected for appointment will, unless the Secretary of State decides otherwise, be required to undergo a course of instruction either at the London School of Hygiene and Tropical Medicine, Endsleigh-gardens, N.W. 1, or at the Liverpool School of Tropical Medicine, Liverpool University, or at Edinburgh University. The cost of tuition will be borne by the Government, but candidates must make their own arrangements for board and lodging; an allowance of £25 a month will be paid to them monthly in arrear while they are under instruction. Payment of the allowance will be made subject to the candidate signing an agreement by which he is bound to refund it (1) if he declines to accept an appointment in any of the Colonies for which he may be selected; (2) if he fails to obtain a certificate or diploma; (3) if he relinquishes the Service for any other reason than mental or physical infirmity, or is removed for misconduct, within three years of his arrival in West Africa.

If at the end of the session there exists no vacancy in the Staff to which a candidate can be appointed, he will be placed in a Reserve and granted an allowance at the rate of £200 a year until the occurrence of a vacancy.

Leave of Absence.—European officers in West Africa may be granted vacation leave on full salary not exceeding in all one week's leave in the United Kingdom for every completed calendar month of total residential service in West Africa, plus the time necessarily taken on the journey to the United Kingdom, and, if the officer is returning to West Africa for further service, the time necessarily taken on the journey from the United Kingdom to the Colony. Vacation leave may be granted without any special grounds after 18 consecutive calendar months of residential service in West Africa. An officer will not be required to serve a tour of more than 24 consecutive calendar months' residential service except in special circumstances; and the Governor may grant vacation leave to any officer at any time after he has completed 12 consecutive calendar months' residential service within the above limits, the actual length of each officer's tour will be at the discretion of the Governor. Vacation leave on full salary may also be granted to an officer if he is invalided from West Africa after less than 12 consecutive calendar months' residential service, and sick leave on full salary may be granted for any period not exceeding six calendar months.

Appointments and Salaries.—Medical officers for the West African Colonies and Protectorates—namely, the Gambia, Sierra Leone, the Gold Coast (including Ashanti and the Northern Territories), and Nigeria (Southern and Northern Provinces)—are selected by the Secretary of State for the Colonies, and are on one list for employment and promotion. The grades and emoluments of the Staff are at present as follows:—

The Director of the Medical and Sanitary Service, Nigeria, receives a salary of £1800 a year, with a duty allowance at the rate of £300 a year. The Director of Medical and Sanitary Service in the Gold Coast receives a salary of £1600 a year, with a duty allowance at the rate of £320 a year. The Director of Medical and Sanitary Service in Sierra Leone receives a salary of £1400 a year, with a duty allowance at the rate of £280 a year. The Deputy Director of Medical and Sanitary Service, Nigeria, and the Deputy Director of Sanitary Service, Nigeria, receive salaries of £1500 a year, with duty allowances at the rate of £300 a year. The Deputy Director of Medical and Sanitary Service, Gold Coast, and the Assistant Director of Medical and Sanitary Services, Nigeria, receive salaries of £1400 a year, with duty allowances at the rate of £280 a year. Assistant Directors Medical Service: There are seven appointments on this grade, five in Nigeria, two in the Gold Coast. The salary is at the rate of £1300 a year, with duty allowance at the rate of £260 a year. The Assistant Director of Sanitary Service, Nigeria, the Deputy Director of Sanitary Service in the Gold Coast and the Deputy Director of Sanitary Service in Sierra Leone receive salary at the rate of £1300 a year, with duty allowance at the rate of £260 a year. Specialists: The number of these appointments is not fixed, officers of outstanding professional merit being eligible for appointment. The salary is at the rate of £1300 a year, with duty allowance at the rate of £260 a year. After five years' approved service as such, the specialist officer is eligible to receive a salary at the rate of £1400 a year, with duty allowance at the rate of £280 a year. There are at present five officers appointed specialists in Nigeria, three in the Gold Coast, and one in Sierra Leone. Senior Medical Officer: There are twenty appointments of this grade, with salary at the rate of £1000 a year, rising by annual increments of £50 to £1150 a year, and seniority allowance at the rate of £100 a year. The Senior Medical Officer, Gambia, is allowed "staff pay" of £150 a year, in addition to duty allowance, but he is debarred from private practice. Senior Sanitary Officer: There are nine appointments of this grade, with salary at the rate of £1050 a year, rising by annual increments of £50 to £1200 a year, and a duty allowance at the rate of £210 a year. Possession of the Diploma in Public Health is usually required for appointment to this grade. Special facilities are granted to study for the diploma during leave. Medical Officers of Health: There are at present 24 appointments of this grade. The salary scale is the same as that of Medical Officers, except that Medical Officers of Health are granted an initial salary at the rate of £800 a year, together with seniority allowance at the rate of £72 a year and staff pay at the rate of £150 a year, half of which is payable during leave. After three years' service on the maximum of the scale, viz., £960 a year, and on undergoing an approved course of study, Medical Officers of Health are eligible, if unpromoted, subject to the recommendation of the Governor, to be placed on the scale £1000 a year rising by annual increments of £50 to £1150 a year, together with seniority allowance at the rate of £100 a year and staff pay as before. The holders of these appointments are not allowed private practice. Candidates selected for service as Medical Officers of Health must obtain the Diploma in Tropical Medicine and Hygiene of Cambridge, London, or Liverpool as a condition of appointment, or must be in possession of the Diploma in Public Health. They are appointed subject to the condition that, if after a period of service in West Africa they are considered unsuitable to serve in that capacity, they may be called upon to transfer to the medical side. In such cases the officers are given the rate of salary which they would have reached if they had been appointed to be Medical Officers instead of Medical Officers of Health in the first instance. Medical Officer: The salary attached to this grade is at the rate of £660 a year, rising by annual increments of £30 to £720 a year. Then, if confirmed in the appointment, £720 a year, rising by annual increments of £40 to £960, with seniority allowance at the rate of £72 a year. Before passing £800, medical officers are required to take a special course of study for three months. If they obtain satisfactory certificates at the end of the course they draw their further increments up to £960 a year.

A medical officer who has served for three years on the maximum salary of this scale (£960) without obtaining promotion is eligible, if recommended by the Governor, to be placed on the scale £1000–£50–£1150, with £100 seniority allowance (as for Senior Medical Officers).

Special Appointments.—The Director of the Medical Research Institute, Lagos, and the Director of the Medical Research Institute, Accra, receive a salary of £1300 a year, with a duty allowance of £260 a year, rising after five years' approved service to a salary at the rate of £1400 a year and duty allowance at the rate of £280 a year. There are a number of appointments for pathologists and bacteriologists in Nigeria and the Gold Coast. The salary and other conditions attached to these posts are similar to those of Medical Officers of Health. Duty allowances, seniority allowance, and staff pay are not pensionable emoluments.

Increments.—Increments to salaries are payable only when the service of an officer during the period of employment qualifying for increment is approved.

Payment of Salaries.—Information as to the payment of officers' salaries or of monthly remittances to persons in England may be obtained from the Crown Agents for the Colonies, 4, Millbank, S.W. 1. All allowances are paid locally.

All officers of the staff, except directors, deputy directors, assistant directors, senior sanitary officers, medical officers of health, research officers, and a few other officers holding special appointments, are at present allowed to take private practice, provided that it does not interfere with the faithful and efficient performance of their official duties, but it is within the power of the Governor to withdraw or suspend the privilege in such places and for such periods as he may consider desirable. Private practice does not exist at many stations, and no guarantee can be given that an officer will be posted to a station in which he will be able to practise privately. As a general rule, and subject to the exigencies of the service, stations where there is private practice are allocated to senior members of the Staff.

Pensions and Gratuities.—Pensions and gratuities on retirement are granted in accordance with the law and regulations of each individual Colony.

Fuller information can be obtained from the Private Secretary, Colonial Office, 2, Richmond-terrace, London, S.W.1.

SUDAN MEDICAL SERVICE.

This Service is responsible for carrying out civil, medical, and public health duties in the Sudan.

The staff consists of: (*a*) A Director, pay £1500–£2000. (*b*) A Senior Physician and a Senior Surgeon to the Khartoum and Omdurman Civil Hospitals, each with a pay of £1200–£1750. Payment of the allowance will be made subject to the candidate signing an agreement by which he is bound to refund it (1) if he declines to accept an appointment in any of the Colonies for which he may be selected; (2) if he fails to obtain a certificate or diploma; (3) if he relinquishes the Service for any other reason than mental or physical infirmity, or is removed for misconduct, within three years of his arrival in West Africa.

If at the end of the session there exists no vacancy in the Staff to which a candidate can be appointed, he will be placed in a Reserve and granted an allowance at the rate of £200 a year until the occurrence of a vacancy.

Leave of Absence.—European officers in West Africa may be granted vacation leave on full salary not exceeding in all one week's leave in the United Kingdom for every completed calendar month of total residential service in West Africa, plus the time necessarily taken on the journey to the United Kingdom, and, if the officer is returning to West Africa for further service, the time necessarily taken on the journey from the United Kingdom to the Colony. Vacation leave may be granted without any special grounds after 18 consecutive calendar months of residential service in West Africa. An officer will not be required to serve a tour of more than 24 consecutive calendar months' residential service except in special circumstances; and the Governor may grant vacation leave to any officer at any time after he has completed 12 consecutive calendar months' residential service within the above limits, the actual length of each officer's tour will be at the discretion of the Governor. Vacation leave on full salary may also be granted to an officer if he is invalided from West Africa after less than 12 consecutive calendar months' residential service, and sick leave on full salary may be granted for any period not exceeding six calendar months.

Appointments and Salaries.—Medical officers for the West African Colonies and Protectorates—namely, the Gambia, Sierra Leone, the Gold Coast (including Ashanti and the Northern Territories), and Nigeria (Southern and Northern Provinces)—are selected by the Secretary of State for the Colonies, and are on one list for employment and promotion. The grades and emoluments of the Staff are at present as follows:—

The Director of the Medical and Sanitary Service, Nigeria, receives a salary of £1800 a year, with a duty allowance at the rate of £360 a year. The Director of Medical and Sanitary Service in the Gold Coast receives a salary of £1600 a year, with a duty allowance at the rate of £320 a year. The Director of Medical and Sanitary Service in Sierra Leone receives a salary of £1400 a year, with a duty allowance at the rate of £280 a year. The Deputy Director of Medical and Sanitary Service, Nigeria, and the Deputy Director of Sanitary Service, Nigeria, receive salaries of £1500 a year, with duty allowances at the rate of £300 a year. The Deputy Director of Medical and Sanitary Service, Gold Coast, and the Assistant Director of Medical and Sanitary Services, Nigeria, receive salaries of £1400 a year, with duty allowances at the rate of £280 a year. Assistant Directors Medical Service: There are seven appointments on this grade, five in Nigeria, two in the Gold Coast. The salary is at the rate of £1300 a year, with duty allowance at the rate of £260 a year. The Assistant Director of Sanitary Service, Nigeria, the Deputy Director of Sanitary Service in the Gold Coast and the Deputy Director of Sanitary Service in Sierra Leone receive salary at the rate of £1300 a year, with duty allowance at the rate of £260 a year. Specialists: The number of these appointments is not fixed, officers of outstanding professional merit being eligible for appointment. The salary is at the rate of £1300 a year, with duty allowance at the rate of £260 a year. After five years' approved service as such, the specialist officer is eligible to receive a salary at the rate of £1400 a year, with duty allowance at the rate of £280 a year. There are at present five officers appointed specialists in Nigeria, three in the Gold Coast, and one in Sierra Leone. Senior Medical Officer: There are twenty appointments of this grade, with salary at the rate of £1000 a year, rising by annual increments of £50 to £1150 a year, and seniority allowance at the rate of £100 a year. The Senior Medical Officer, Gambia, is allowed "staff pay" of £150 a year, in addition to duty allowance, but he is debarred from private practice. Senior Sanitary Officer: There are nine appointments of this grade, with salary at the rate of £1050 a year, rising by annual increments of £50 to £1200 a year, and a duty allowance at the rate of £210 a year. Possession of the Diploma in Public Health is usually required for appointment to this grade. Special facilities are granted to study for the diploma during leave. Medical Officers of Health: There are at present 24 appointments of this grade. The salary scale is the same as that of Medical Officers, except that Medical Officers of Health are granted an initial salary at the rate of £800 a year, together with seniority allowance at the rate of £72 a year and staff pay at the rate of £150 a year, half of which is payable during leave. After three years' service on the maximum of the scale, viz., £960 a year, and on undergoing an approved course of study, Medical Officers of Health are eligible, if unpromoted, subject to the recommendation of the Governor, to be placed on the scale £1000 a year rising by annual increments of £50 to £1150 a year, together with seniority allowance at the rate of £100 a year and staff pay as before. The holders of these appointments are not allowed private practice. Candidates selected for service as Medical Officers of Health must obtain the Diploma in Tropical Medicine and Hygiene of Cambridge, London, or Liverpool as a condition of appointment, or must be in possession of the Diploma in Public Health. They are appointed subject to the condition that, if after a period of service in West Africa they are considered unsuitable to serve in that capacity, they may be called upon to transfer to the medical side. In such cases the officers are given the rate of salary which they would have reached if they had been appointed to be Medical Officers instead of Medical Officers of Health in the first instance. Medical Officer: The salary attached to this grade is at the rate of £660 a year, rising by annual increments of £30 to £720 a year. Then, if confirmed in the appointment, £720 a year, rising by annual increments of £40 to £960, with seniority allowance at the rate of £72 a year. Before passing £800, medical officers are required to take a special course of study for three months. If they obtain satisfactory certificates at the end of the course they draw their further increments up to £960 a year.

A medical officer who has served for three years on the maximum salary of this scale (£960) without obtaining promotion is eligible, if recommended by the Governor, to be placed on the scale £1000–£50–£1150, with £100 seniority allowance (as for Senior Medical Officers).

Special Appointments.—The Director of the Medical Research Institute, Lagos, and the Director of the Medical Research Institute, Accra, receive a salary of £1300 a year, with a duty allowance of £260 a year, rising after five years' approved service to a salary at the rate of £1400 a year and duty allowance at the rate of £280 a year. There are a number of appointments for pathologists and bacteriologists in Nigeria and the Gold Coast. The salary and other conditions attached to these posts are similar to those of Medical Officers of Health. Duty allowances, seniority allowance, and staff pay are not pensionable emoluments.

Increments.—Increments to salaries are payable only when the service of an officer during the period of employment qualifying for increment is approved.

Payment of Salaries.—Information as to the payment of officers' salaries or of monthly remittances to persons in England may be obtained from the Crown Agents for the Colonies, 4, Millbank, S.W. 1. All allowances are paid locally.

All officers of the staff, except directors, deputy directors, assistant directors, senior sanitary officers, medical officers of health, research officers, and a few other officers holding special appointments, are at present allowed to take private practice, provided that it does not interfere with the faithful divided into two parts, of which the first is concerned with bacteriological principles and with general technique. The second part of the course is to be devoted to bacteriology applied to (1) clinical medicine, (2) hygiene, or (3) industry, at the selection of the candidate.

Public Health: Epidemiology and Vital Statistics.—A course in Epidemiology and Vital Statistics is provided by the London School of Hygiene and Tropical Medicine, under Prof. Greenwood, at the National Institute for Medical Research, Hampstead. Preference is given to medical graduates, and students cannot normally be admitted for a course of less than three months.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.

The Universities of Cambridge, London, Durham, Leeds, Manchester, Edinburgh, Dublin, National University of Ireland, and the Conjoint Board of the R.C.P. Lond. and R.C.S.Eng. now grant diplomas in psychological medicine under conditions that are fairly comparable in the standard of the tests and in the duration of the courses; the details on these points can be obtained from the various examination bodies.

In London, courses of instruction for the Diploma in Psychological Medicine are given annually at the Maudsley Hospital, Denmark Hill, which has recently been definitely recognised as a school of the University of London. The course consists of two parts, commencing in January, and is adapted for the diploma of the Conjoint Board, the University of London, or the University of Cambridge. The parts may be taken separately; also during the year there are other short courses, lectures and demonstrations in psychological medicine.

Maudsley Hospital.—Appointments as clinical assistants are obtainable at the Maudsley Hospital. The holding of such appointments for varying periods satisfies the requirements of the different examining bodies in respect of practical study of mental disorders. The appointments and other facilities for clinical experience are open to qualified medical practitioners apart from the courses of instruction. Inquiries as to lectures should be addressed to the Director of the Central Pathological Laboratory, Maudsley Hospital, Denmark Hill, S.E.: and as to clinical facilities, to the Medical Superintendent at the same address.

Bethlem Royal Hospital.—A course of lectures and practical instruction for the Diploma in Psychological Medicine, granted by the various universities and the Conjoint Board, is held at Bethlem Royal Hospital, London, S.E., twice annually, during the spring and autumn. The fee for the full course is 15 guineas. Part A or Part B, however, may be taken separately at a fee of 10 guineas per part. In addition to the above, clinical instruction in Psychological Medicine is given at Bethlem Royal Hospital every morning (except Wednesdays) at 11 A.M. The fee for students is 3 guineas for a period of three months' attendance and for post-graduates a fee of 5 guineas for a like period. A reduction is made to those who attend the Diploma Course. House physicians are appointed at Bethlem Royal Hospital for a term of six months, which may be extended. These appointments are made on May 1st and Nov. 1st in each year and the vacancies are advertised in the medical papers. Apartments, complete board, attendance, and laundry are provided and also a salary at the rate of £100 per annum. Clinical assistants are often appointed from time to time for periods of three months or longer. These are non-salaried and non-resident posts, but partial board is provided. The Physician-Superintendent, Bethlem Royal Hospital, will supply further particulars.

University of Edinburgh.—Candidates for the Diploma in Psychiatry must be graduates in medicine and surgery of the University of Edinburgh or hold corresponding registrable degrees or qualifications of some other licensing body. Candidates are required subsequent to the date of graduation or obtaining a registrable qualification to have held (*a*) a resident appointment for one year in a hospital for mental disorders approved by the Faculty of Medicine, or alternatively (*b*) a six months' appointment as defined in (*a*) and six months' practical study of nervous diseases in a special or general hospital approved by the Faculty of Medicine. There are two examinations for the Diploma. Part I. comprises 1. Anatomy of the Nervous System. 2. Physiology of the Nervous System. 3. Psychology and Experimental Psychology. Part II. comprises: 1. Neuropathology. 2. Clinical Psychiatry. 3. Clinical Neurology. 4. An additional subject selected by the candidate from a prescribed list. The examinations are held twice yearly in March and July. Candidates who have held an asylum appointment for a period of five years or more may be exempted from the course of study in one or more subjects of the curriculum. Full particulars can be obtained from the Dean of the Faculty of Medicine.

Dublin University.—A post-graduate diploma in Psychological Medicine is conferred upon registered medical practitioners who have held a resident medical appointment at a recognised institution for the treatment of Mental Diseases for 12 months, or who have held such an appointment for six months and have attended clinical instruction at an approved institution for six months. Candidates must also attend special courses of instruction and pass a special examination. Details can be obtained from the Registrar of the School of Physic, Trinity College, Dublin.

The National University of Ireland and the *Conjoint Board of the Royal Colleges of Ireland*[*] confer a diploma in Psychological Medicine upon similar terms; application should be made to the Registrar of the School of Physic and the Secretary of the Board respectively.

DIPLOMA IN OPHTHALMIC MEDICINE.

Special diplomas in ophthalmic medicine and surgery are issued by two examining bodies.

University of Oxford.—The diploma in ophthalmology (D.O.) is granted to registered medical practitioners after passing an examination, held annually in March, which is open to candidates who have pursued at Oxford a course of study in ophthalmology over a period of at least two months and who have attended a 12 months' recognised hospital course. Further information regarding these requirements may be obtained from the Dean of the School of Medicine.

Conjoint Board R.C.P. Lond., R.C.S. Eng.—The Conjoint Board grants the D.O.M.S. after an examination held in two parts, twice yearly in February and July. Part I. comprises anatomy and embryology of the visual apparatus, physiology of vision, and elementary optics. Part II. comprises optical defects, ophthalmic medicine and surgery, and pathology with special reference to ophthalmology. The examination in each case is written, oral, and practical or clinical. Candidates may only enter for Part II. on completion of a year of special study of ophthalmology after obtaining a registrable diploma or a Degree in Medicine and Surgery of a University recognised by the Board.

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.

University of Cambridge.—The D.M.R.E. is open only to those who have held for at least one year a medical qualification approved by the Committee. The new regulations, which come into operation this year, in some respects materially alter the scope of

[*] No returns.

SPECIAL DIPLOMAS.

DIPLOMA IN TROPICAL MEDICINE.

ALTHOUGH a qualification in tropical medicine has not been made registrable by statute, a diploma is regarded as indispensable for appointments in the Colonial Medical Service and similar positions abroad. Systematic instruction for these diplomas is given at the Incorporated Liverpool School of Tropical Medicine (founded in 1898) and at the London School of Hygiene and Tropical Medicine, 23, Endsleigh-gardens, Euston-road, N.W.; while the Universities of Cambridge, London, Edinburgh, and the English Conjoint Board grant the diploma.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE (*University of London*).—The Departments of Bacteriology and Immunology under Prof. Topley, and of Epidemiology and Vital Statistics under Prof. Greenwood, will continue their advanced courses of study in October next, the Bacteriology course (covering the new Diploma) at 6, Gordon-square, W.C., and the Epidemiology course at the National Institute for Medical Research at Hampstead. The existing Departments of the School dealing with the courses of study for Tropical Medicine and Hygiene will continue for the present in the building occupied by the Hospital for Tropical Diseases at Endsleigh-gardens. There are two such courses in the year, each lasting 20 weeks, inclusive of examinations. The dates for the commencement of each course are Oct. 1st, 1928, and March 11th, 1929, respectively. The course covers the work required for the D.T.M. and H. (England) and part of that required for the M.D. in Tropical Medicine of the University of London. For facilities for clinical and pathological study the School is indebted to the Seamen's Hospital Society, who, prior to August 1st, 1924, were responsible for the London School of Tropical Medicine. The new building in which the School will be housed is approaching completion, and the formal opening and the commencement of the new courses of study (in particular that of the D.P.H.) will probably be in the summer or autumn of next year. Research studentships and scholarships are available, and full particulars with regard to these and the courses of study generally may be obtained from the Secretary of the School, Malet-street, London, W.C. 1.

University of Liverpool.—The University grants a Diploma in Tropical Medicine. At the end of each full course an examination is held by the University for its Diploma of Tropical Medicine (D.T.M.), which is open only to those who have been through the course of instruction of the school. The subjects of examination are (*a*) Tropical Pathology, Tropical Parasitology; (*b*) Entomology; (*c*) Tropical Hygiene and Sanitation; (*d*) Tropical Medicine, including Ætiology, Symptoms, Diagnosis, and Treatment of Tropical Diseases. The advanced course consists entirely of Practical and Clinical Laboratory Work, given at the laboratory at the University. Applications should be made to the Dean of the Medical Faculty, University of Liverpool.

The University also grants a diploma in Tropical Hygiene (D.T.H.). The subjects of examination are Bacteriology, Chemistry (including Meteorology and Climatology), Parasitology and Entomology, Tropical Sanitation (including Sanitary Engineering), Practical Sanitation, Sanitary Engineering, Statistics. Two University Fellowships of £100 a year each are open to students of the school, amongst others. Accommodation for research work is to be had at the University Laboratory. The Mary Kingsley Medal is awarded by the school for distinguished work in connexion with Tropical Medicine.

University of Cambridge.—The examination for the Diploma in Tropical Medicine and Hygiene is divided into two parts. Part I. is held in Cambridge in April and Part II. in July in London. Candidates for Part I. are examined under the same regulations and in the same subjects as candidates for the Diploma in Public Health, but any qualification in medicine or surgery recognised by the proper authority of any country outside the British Dominions may be recognised. The subjects for Part II. are Medicine, Surgery, and Hygiene in their relation to Tropical Disease.

The examination will be partly in writing, partly oral, and partly practical or clinical (the clinical part will be conducted at a hospital for tropical diseases, at which cases will be submitted for diagnosis and comment). Every candidate who passes the examination to the satisfaction of the examiners will receive from the University a diploma (D.T.M. & H.) testifying to his knowledge and skill in tropical medicine and hygiene.

Further information respecting the courses of study and examinations may be obtained from Mr. J. E. Purvis, Public Health Chemical Laboratory, Cambridge.

University of Edinburgh.—Candidates for the Diploma in Tropical Medicine and Hygiene must be graduates in medicine and surgery of the University of Edinburgh or hold corresponding registrable degrees or qualifications of some other licensing body. The course of instruction, comprising a primary and a second course, is given during the autumn and spring terms, October to March, and includes Tropical Hygiene, Bacteriology, Entomology and Parasitology, Diseases of Tropical Climates (systematic and clinical), Tuberculosis, and Venereal Diseases. The primary course alone is also given during the summer term, April to June. Provision is made in the University for instruction in all subjects. The examinations are written, oral, and practical, and are held at the end of the courses. Candidates are required on the first occasion of presenting themselves for examination to appear for all the subjects. Candidates who fail to pass the entire examination within a period of 12 months after first appearance are required to reappear for all the subjects. The University is included in the list of Institutions whose courses of instruction in Tropical Medicine may be taken by officers on appointment to the Colonial Medical Services or during study-leave. Full particulars can be obtained from the Dean of the Faculty of Medicine.

Conjoint Board R.C.P. Lond., R.C.S. Eng.—The diploma of D.T.M. & H. Eng. is awarded on the results of an examination held twice yearly, in February and July. Candidates must possess a registrable qualification, and produce evidence of having attended (1) practical instruction in pathology, protozoology, helminthology, entomology, bacteriology, and hygiene in relation to tropical medicine in a recognised institution during not less than five months; (2) clinical practice of a recognised hospital for the same period. Conditions of study may be modified in the case of candidates of special experience. Notice of entry to the Secretary, Examination Hall, Queen-square, London, W.C.1.

DIPLOMA IN BACTERIOLOGY.

The University of London has instituted an academic diploma in bacteriology, and a full time course covering this diploma will be given in October by the London School of Hygiene and Tropical Medicine. This course will be held at 6, Gordon-square, London, W.C. 1, pending the opening of the new buildings behind the British Museum which are now under construction. The diploma is open to graduates in medicine, science, or pharmacy of London or of any other approved university. Registered medical practitioners or other non-graduate students who have obtained a qualification and undergone a previous training which in the opinion of the University has fitted them to profit by the instruction may be admitted. The course of study, which extends over an academic year, is

Candidates will be admissible to Examination in Part I. on producing evidence:—

1. Of being in possession of a registrable qualification in Medicine, Surgery, and Midwifery.

2. Of having attended during a period of not less than five months at an Institution recognised by the Examining Board in England, practical instruction in (a) Bacteriology and Parasitology (including Medical Entomology) especially in their relation to diseases of man and to those diseases of the lower animals which are transmissible to man, during 180 hours, of which not less than 150 hours have been occupied in practical laboratory work. (b) Chemistry and Physics in relation to public health, during 90 hours, of which not less than 70 hours have been occupied in practical laboratory work. (c) Meteorology and Climatology in relation to public health, during not less than 10 hours.

Candidates will be admitted to Part II. of the Examination on producing evidence:—

1. Of having been in possession of a registrable qualification in Medicine, Surgery, and Midwifery during not less than two years, of being registered by the General Medical Council, and of having completed the curriculum for the Diploma extending over a period of 12 calendar months subsequent to the attainment of a registrable qualification.

2. Of having attended, after obtaining the registrable Qualification, instruction during not less than 80 hours at an Institution recognised by the Examining Board in England in the following subjects:—(a) The Principles of Public Health and Sanitation for not less than 30 hours; (b) Epidemiology and Vital Statistics for not less than 20 hours; (c) Sanitary Law and Administration (including Public Medical Services) during not less than 20 hours; (d) Sanitary Construction and Planning during not less than 10 hours.

3. Of having attended for three months the clinical practice of a hospital for infectious diseases recognised by the Examining Board in England and of having therein received instruction in the methods of administration. The certificate must state that the candidate has attended on one or more days in each week of the three months, that each attendance was of two hours' duration, with a total attendance of 60 hours.

4. Of having been engaged during a period of not less than six months in acquiring a practical knowledge of the duties, routine and special, of public health administration under the supervision of a Medical Officer of Health, and of having received, from such officer or other competent Medical Officer during not less than three hours on each of 60 working days, practical instruction in those duties and also those relating to: (a) Maternity and Child Welfare Service; (b) Health Service for children of school age, (c) Venereal Diseases Service; (d) Tuberculosis Service; (e) Industrial Hygiene; (f) Inspection and Control of Food; including meat and milk.

The above certificate (4) must be obtained from a Medical Officer of Health who devotes his whole time to public work, or from a Medical Officer of Health of a Sanitary Area having a population of not less than 50,000, or in Ireland the Medical Superintendent Officer of Health of a County or County Borough having a population of not less than 50,000.

University of Oxford.—An examination, conducted partly in writing, partly vivâ voce, and in each subject partly practical, is held in Michaelmas and in Trinity Term in the following subjects:—General Hygiene, General Pathology (with special relation to Infectious Diseases), the Laws relating to Public Health, Sanitary Engineering, Vital Statistics. The examination is in two parts, which may be taken together or separately; but Part I. must be passed either before or at the same examination as Part II.

The First Part of the examination will comprise (a) written papers of three hours each in (i.) Chemistry and Physics, and (ii.) Pathology and Bacteriology; (b) a three hours' practical and vivâ voce examination in Chemistry and Physics; (c) a three hours' practical and vivâ voce examination in Pathology and Bacteriology.

The Second Part of the Examination will consist of the following parts:—(a) Two written papers, each of three hours, dealing with General Hygiene (including Sanitary Engineering, Vital Statistics, and the Laws relating to Public Health); (b) a practical and vivâ voce examination in General Hygiene; and (c) a three hours' practical and vivâ voce examination in Pathology and Bacteriology.

Candidates in Part I. of the examination will be required to produce certificates (1) of Laboratory Work in Chemistry, Physics, Meteorology, and Climatology as applied to Hygiene, and (2) of having had Practical Instruction in Bacteriology and Parasitology and the Pathology of the Diseases of Animals transmissible to Man.

Candidates in Part II. will produce the following further certificates: (3) of a Practical Knowledge of the Duties, Routine and Special, of Public Health Administration; and (4) of having attended the practice of a Hospital for Infectious Diseases at which opportunities are afforded for the study of the Methods of Administration.

All the above degrees are now open to Women Students, and particulars of Scholarships and Prizes may be obtained from the Principals of the various Ladies' Colleges. The names of candidates for the Diploma in Public Health must be sent to the Assistant Registrar of the University, Clarendon Building, Oxford. Applications for any further information should be addressed to the Dean, Department of Medicine, Museum, Oxford.

University of Cambridge.—Two examinations in so much of State medicine as is comprised in the functions of medical officers of health are held during the year. The examination is divided into two parts and demands proficiency in all the branches of study which bear upon the duties of medical officers of health. The examinations in both parts will be oral and practical, as well as in writing. Candidates may present themselves for either part separately or for both together at their option; but the result of the examination in the case of any candidate will not be published until he has satisfied the examiners in both parts. Marks of distinction will be placed against the names of candidates who have specially distinguished themselves in either (1) Part I. of the examination; or (2) Part II. of the examination. Candidates must before admission to either part of the examination produce evidence of having satisfied the regulations applicable to Part I. and Part II. The examination for Part I. is in April and for Part II. in October.

For Part I. of the examination courses of lectures and laboratory instruction are given in the University on Hygiene, Chemistry, &c., and on Bacteriology and Parasitology. For Part II. the Medical Officer of Health for Cambridge gives courses on Practical Sanitary Administration and in the Administrative Methods of the Infectious Diseases Hospital; and the Medical Officer of Health to the Cambridgeshire County Council, on Sanitary Laws, School Hygiene, Epidemiology. There are also courses by special lecturers in Vital Statistics, Tuberculosis Service, Venereal Diseases Service, Industrial Hygiene, Maternity and Child Welfare. These courses are open to non-members of the University.

A special Diploma in Hygiene is granted to medical graduates whose qualifications are not registrable in England. The courses and examinations are the same as for the Diploma in Public Health (except that the candidates are not examined in English Sanitary Laws).

All applications for further information respecting examinations and the courses of study should be addressed to Mr. Purvis, Public Health Chemical Laboratory, Cambridge.

University of London.—Candidates for the M.D. Degree may offer State Medicine as a subject in which to graduate. The regulations have been revised and may be obtained on application to the Academic Registrar, University of London, South Kensington.

University of Durham.—The Degree of Bachelor of Hygiene (B.Hy.) and the Diploma in Public Health (D.P.H.).—No candidate is admitted to the final examination for the Degree of B.Hy. unless he is a Bachelor of Medicine and Surgery, of not less than two years' standing, of a recognised University whose degrees are registrable on the books of the General Medical Council of the United Kingdom, and no candidate is admitted to the final examination the Diploma. The course now occupies nine months, beginning in October. The first three months, which can be spent either in Cambridge or in London, are occupied with lectures and practical work in Physics in preparation for the examination for Part I. in January, and an introductory course in Radiology and Electrology. The second three months must be spent in London. The course includes lectures and clinical instruction in Radiology and Electrology, with clinical practice in the radiological department of a hospital approved for that purpose by the Committee. The examination for Part II. is held in April. During the final three months a candidate must hold a clinical clerkship or similar appointment in a radiological department approved by the Committee, and must then present a thesis in the form of a critical report with notes upon six cases either in Radiology or in Electrology or in both these subjects, illustrating various methods of diagnosis or treatment. A number of large provincial hospitals have been approved by the Committee to take clinical assistants for this part of the course.

Further particulars as to courses and examinations may be obtained from G. Stead, M.A., Cavendish Laboratory, Cambridge, or from Dr. Stanley Melville, British Institute of Radiology, 32, Welbeck-street, London, W. 1.

University of Liverpool.—Candidates before admission to the examination for this diploma must possess a registrable qualification, approved by the University in medicine and surgery, and must have attended courses of instruction in (*a*) physics (two terms), (*b*) (*i*) *radiology, and* (*ii*) *electrology during* six months in the X ray and electrotherapeutic departments of a hospital or hospitals. An examination is held in March each year, the subjects being (*a*) physics, (*b*) radiology and electrology. Examination in either part may be taken separately. Fees: tuition, £24 5*s.*; examination and diploma, £6 5*s.* These courses commence during the first week in October. Application should be made to the Dean, Faculty of Medicine, the University of Liverpool.

University of Edinburgh.—Candidates for the Diploma in Radiology (D.R. Univ. Edin.) must be graduates in medicine and surgery of the University of Edinburgh or hold corresponding registrable degrees or qualification from some other licensing body. Candidates are not admitted to the examination for the Diploma until after the lapse of not less than one year from obtaining a registrable qualification, which qualification must be registered before admission to the Examination. The course of study begins in October and extends over a period of not less than three terms. The Examination, which is written, oral, and practical, is in two parts: (*a*) Physics, and (*b*) Radiology. The Examination is held twice yearly —viz., July and October. Full particulars may be obtained from the Dean of the Faculty of Medicine.

DIPLOMA IN LARYNGOLOGY AND OTOLOGY.

The Conjoint Board R.C.P. Lond., R.C.S. Eng., grants the D.L.O. after an examination held in two parts, twice yearly, in June and December. Part I. comprises anatomy, embryology, and physiology of the ear, nose, pharynx, larynx, trachea and bronchi, and œsophagus. Part II. comprises the medicine, surgery, and pathology of the ear, nose, pharynx, larynx, trachea and bronchi, and œsophagus, and the recognition and use of special instruments and appliances. The examination in each case is written, oral, and practical or clinical. Candidates may only enter for Part II. on completion of one year of special study of the diseases of the ear, nose, pharynx, and larynx, after obtaining a registrable qualification, or a degree in medicine and surgery of a University recognised by the Board. The fee for admission to each part is 6 guineas.

DIPLOMA IN TUBERCULOUS DISEASES.

A Diploma in Tuberculous Diseases is given by the University of Wales. Candidates must possess a medical qualification registrable for practice in Great Britain and Ireland, and be not less than 25 years of age, and either (Category A) have held, for a period of not less than five years, whole-time appointments for work in tuberculosis; or (Category B) have held a registrable qualification to practise for at least one year, and presented (*a*) a certificate of satisfactory pursuance of a course of consecutive post-graduate study of the clinical and epidemiological aspects of tuberculosis of six months' duration at a recognised university, medical school, or hospital where such a course is given; or, alternatively, a certificate of one year's post-graduate work as a whole-time member of the staff of a tuberculosis hospital, sanatorium, or dispensary approved by the Ministry of Health, signed by the representative of the authorities for whom the work was performed or by the administrative medical officer concerned; (*b*) a certificate of satisfactory pursuance of a course of consecutive post-graduate practical study of the Pathology and Bacteriology of Tuberculosis of three months' duration at a tuberculosis laboratory or a recognised general laboratory where such a course is given; (*c*) a certificate of three months' satisfactory attendance at a tuberculosis institute or dispensary.

The examination is divided into two parts and the fee is £10 10*s.* Applications should be made to the Registrar of the University, University Registry, Cathays Park, Cardiff, not later than May 15th. The above regulations apply up to and including the next examination, to be held in June, 1929. New regulations, particulars of which may be obtained on application to the Registrar, will come into force for 1930.

The Cecil Prosser Research Scholarship, of the value of £250 for one year, is awarded triennially for research in Tuberculosis.

DIPLOMA IN PUBLIC HEALTH.

THE following epitomises the instruction given at various universities and centres of medical education to medical men desiring to obtain diplomas in sanitary science, public health, hygiene or State medicine, as this discipline is variously called. Resolutions, designed with a view of ensuring "the possession of a distinctively high proficiency, scientific and practical, in all the branches of study which concern the public health," have been adopted at various times by the General Medical Council. The diploma is registrable by the Council, whose rules on the curriculum become *binding on the educational* bodies concerned. The new regulations, which came into force in 1924, extend the period of study and postpone the granting of a diploma until at least two years from qualification.

Conjoint Board of the R.C.P. Lond. and R.C.S. Eng. New regulations came into force on Jan. 1st, 1924, which apply to all candidates who have not commenced bona-fide study of Public Health in accordance with the above regulations before that date. They are as follows: *The Examination* consists of two Parts. Part I. will be held in the months of January, April, and June, and Part II. in the months of January, April, and July in each year. Candidates may enter for Parts I. and II. separately or at the same time, but they must pass Part I. before proceeding to Part II. The Examination in each part will be written, oral, and practical. Part II. will include a practical examination in Infectious *Diseases, Food Inspection*, and Inspection of selected Premises. Candidates who fail to satisfy the Examiners in either part may present themselves again at the next *Examination on* payment of the same fees. Candidates intending to present themselves for either part of the Examination must give 11 days' notice in writing to the Secretary, at the Examination Hall, Queen-square, London, W.C. 1.

Candidates will be admissible to Examination in Part I. on producing evidence :—

1. Of being in possession of a registrable qualification in Medicine, Surgery, and Midwifery.

2. Of having attended during a period of not less than five months at an Institution recognised by the Examining Board in England, practical instruction in (*a*) Bacteriology and Parasitology (including Medical Entomology) especially in their relation to diseases of man and to those diseases of the lower animals which are transmissible to man, during 180 hours, of which not less than 150 hours have been occupied in practical laboratory work. (*b*) Chemistry and Physics in relation to public health, during 90 hours, of which not less than 70 hours have been occupied in practical laboratory work. (*c*) Meteorology and Climatology in relation to public health, during not less than 10 hours.

Candidates will be admitted to Part II. of the Examination on producing evidence :—

1. Of having been in possession of a registrable qualification in Medicine, Surgery, and Midwifery during not less than two years, of being registered by the General Medical Council, and of having completed the curriculum for the Diploma extending over a period of 12 calendar months subsequent to the attainment of a registrable qualification.

2. Of having attended, after obtaining the registrable Qualification, instruction during not less than 80 hours at an Institution recognised by the Examining Board in England in the following subjects :—(*a*) The Principles of Public Health and Sanitation for not less than 30 hours; (*b*) Epidemiology and Vital Statistics for not less than 20 hours; (*c*) Sanitary Law and Administration (including Public Medical Services) during not less than 20 hours; (*d*) Sanitary Construction and Planning during not less than 10 hours.

3. Of having attended for three months the clinical practice of a hospital for infectious diseases recognised by the Examining Board in England and of having therein received instruction in the methods of administration. The certificate must state that the candidate has attended on one or more days in each week of the three months, that each attendance was of two hours' duration, with a total attendance of 60 hours.

4. Of having been engaged during a period of not less than six months in acquiring a practical knowledge of the duties, routine and special, of public health administration under the supervision of a Medical Officer of Health, and of having received, from such officer or other competent Medical Officer during not less than three hours on each of 60 working days, practical instruction in those duties and also those relating to: (*a*) Maternity and Child Welfare Service; (*b*) Health Service for children of school age; (*c*) Venereal Diseases Service; (*d*) Tuberculosis Service; (*e*) Industrial Hygiene; (*f*) Inspection and Control of Food; including meat and milk.

The above certificate (4) must be obtained from a Medical Officer of Health who devotes his whole time to public work, or from a Medical Officer of Health of a Sanitary Area having a population of not less than 50,000, or in Ireland the Medical Superintendent Officer of Health of a County or County Borough having a population of not less than 50,000.

University of Oxford.—An examination, conducted partly in writing, partly vivâ voce, and in each subject partly practical, is held in Michaelmas and in Trinity Term in the following subjects :—General Hygiene, General Pathology (with special relation to Infectious Diseases), the Laws relating to Public Health, Sanitary Engineering, Vital Statistics. The examination is in two parts, which may be taken together or separately; but Part I. must be passed either before or at the same examination as Part II.

The First Part of the examination will comprise (*a*) written papers of three hours each in (i.) Chemistry and Physics, and (ii.) Pathology and Bacteriology; (*b*) a three hours' practical and vivâ voce examination in Chemistry and Physics; (c) a three hours' practical and vivâ voce examination in Pathology and Bacteriology.

The Second Part of the Examination will consist of the following parts :—(*a*) Two written papers, each of three hours, dealing with General Hygiene (including Sanitary Engineering, Vital Statistics, and the Laws relating to Public Health); (*b*) a practical and vivâ voce examination in General Hygiene; and (*c*) a three hours' practical and vivâ voce examination in Pathology and Bacteriology.

Candidates in Part I. of the examination will be required to produce certificates (1) of Laboratory Work in Chemistry, Physics, Meteorology, and Climatology as applied to Hygiene, and (2) of having had Practical Instruction in Bacteriology and Parasitology and the Pathology of the Diseases of Animals transmissible to Man.

Candidates in Part II. will produce the following further certificates: (3) of a Practical Knowledge of the Duties, Routine and Special, of Public Health Administration; and (4) of having attended the practice of a Hospital for Infectious Diseases at which opportunities are afforded for the study of the Methods of Administration.

All the above degrees are now open to Women Students, and particulars of Scholarships and Prizes may be obtained from the Principals of the various Ladies' Colleges. The names of candidates for the Diploma in Public Health must be sent to the Assistant Registrar of the University, Clarendon Building, Oxford. Applications for any further information should be addressed to the Dean, Department of Medicine, Museum, Oxford.

University of Cambridge.—Two examinations in so much of State medicine as is comprised in the functions of medical officers of health are held during the year. The examination is divided into two parts and demands proficiency in all the branches of study which bear upon the duties of medical officers of health. The examinations in both parts will be oral and practical, as well as in writing. Candidates may present themselves for either part separately or for both together at their option; but the result of the examination in the case of any candidate will not be published until he has satisfied the examiners in both parts. Marks of distinction will be placed against the names of candidates who have specially distinguished themselves in either (1) Part I. of the examination; or (2) Part II. of the examination. Candidates must before admission to either part of the examination produce evidence of having satisfied the regulations applicable to Part I. and Part II. The examination for Part I. is in April and for Part II. in October.

For Part I. of the examination courses of lectures and laboratory instruction are given in the University on Hygiene; Chemistry, &c., and on Bacteriology and Parasitology. For Part II. the Medical Officer of Health for Cambridge gives courses on Practical Sanitary Administration and in the Administrative Methods of the Infectious Diseases Hospital; and the Medical Officer of Health to the Cambridgeshire County Council, on Sanitary Laws, School Hygiene, Epidemiology. There are also courses by special lecturers in Vital Statistics, Tuberculosis Service, Venereal Diseases Service, Industrial Hygiene, Maternity and Child Welfare. These courses are open to non-members of the University.

A special Diploma in Hygiene is granted to medical graduates whose qualifications are not registrable in England. The courses and examinations are the same as for the Diploma in Public Health (except that the candidates are not examined in English Sanitary Laws).

All applications for further information respecting examinations and the courses of study should be addressed to Mr. Purvis, Public Health Chemical Laboratory, Cambridge.

University of London.—Candidates for the M.D. Degree may offer State Medicine as a subject in which to graduate. The regulations have been revised and may be obtained on application to the Academic Registrar, University of London, South Kensington.

University of Durham.—The Degree of Bachelor of Hygiene (B.Hy.) and the Diploma in Public Health (D.P.H.).—No candidate is admitted to the final examination for the Degree of B.Hy. unless he is a Bachelor of Medicine and Surgery, of not less than two years' standing, of a recognised University whose degrees are registrable on the books of the General Medical Council of the United Kingdom, and no candidate is admitted to the final examination for the D.P.H. unless he is a registered medical practitioner, of not less than two years' standing. The course of study for the B.Hy. and D.P.H. extends over a period of not less than 12 calendar months, subsequent to the attainment of a qualification registrable by the General Medical Council of the United Kingdom. Candidates for the B.Hy. must attend this course at the University of Durham; candidates for the D.P.H. may attend it at the University of Durham, or at any medical school or institution which is recognised by the University. The examination for the diploma or degree is divided into two parts. A candidate must pass in all the subjects of Part I. before being admitted to examination for Part II. In Part I., and also in Part II., a candidate must pass in all the specified subjects at one time. The examination for Part I. is practical, written, and oral, and includes the following subjects: Bacteriology and Parasitology (including medical entomology); Chemistry and Physics, and Meteorology and Climatology, in relation to Public Health. Candidates are not admitted to examination for Part I. until after they have completed the prescribed courses of instruction in the subjects thereof. The examination for Part II. includes Hygiene and Sanitation (comprising sanitary construction), Epidemiology and Infectious Diseases; Sanitary Law and Vital Statistics; Public Health Administration. The examination is written and oral, and includes practical examinations in Infectious Diseases, Food Inspection, Inspection of Premises—Dwellings, Factories, Workshops, Schools, &c. Candidates are not admitted to examination for Part II. until after they have completed the prescribed courses of instruction in the subjects thereof. Doctor of Hygiene (D.Hy.): Candidates must be Bachelors of Hygiene of the University of two years' standing, and are required to satisfy the examiners that they have conducted original research in the subject of Public Health.

Victoria University of Manchester.—An examination in Public Health is held twice yearly. The examination is in two parts and is written, oral, and practical. Candidates may present themselves for Parts I. and II. separately or at the same time provided that no candidate be admitted to Part II. unless he has already passed in Part I. No candidate's name will be published until he has satisfied the examiners in both parts of the examination. Every candidate who has passed both parts of the examination to the satisfaction of the examiners, and who is legally registered, will receive a Diploma in Public Health. The examination will begin about the middle of July and the middle of October in each year. Holders of the Diploma in Public Health are eligible for examination for the Certificates in School Hygiene and Factory Hygiene after attending the prescribed periods of study and hospital practice. An examination for a Diploma in Bacteriology is held for graduates in science or medicine who have attended prescribed courses for at least one academic year; candidates must present a satisfactory thesis on an approved subject.

University of Birmingham.—Under the revised rules and regulations of the General Medical Council the University grants a degree of B.Sc. in Public Health and also a Diploma in the same subject on the following conditions: Graduates in Medicine of this University may become candidates for the degree of Bachelor of Science in Public Health by conforming to all the requirements laid down for candidates for the Diploma in Public Health, except that after graduating in Medicine all courses of study must be taken out in the University, and they must, in addition, have attended a three months' course of Geology in the University. A Thesis on the Ætiology and Prevention of a Disease of which the candidate has made a special study must be submitted on entry for B.Sc. Part II. The examinations will be held in the months of March and October, and will consist of two parts, each part being written, oral, and practical. No candidate will be allowed to pass Part II. until he has passed Part I. Candidates may enter for Parts I. and II. separately or at the same time. The fee for each part of the examination is £6 5s. Medical Officers of the Royal Navy who have attended the required course of study at the Naval Medical School, Greenwich, will be admitted to Part I. examinations for the Diploma in Public Health, whether they have previously been students at the Birmingham School or not; and the same applies to officers of the Royal Army Medical Corps who have studied at the Staff College. Medical Officers of the Navy and Army are admitted to Part II. Examination (D.P.H.) on complying with the requirements laid down for attendance upon Courses of Study. These Courses need not necessarily be attended in the University of Birmingham.

University of Liverpool.—The University grants a Degree in Hygiene (M.H.) and a Diploma (D.P.H.), and every facility is afforded for training in Sanitary Science and State Medicine. The curriculum for the Degree extends over a period of two years, the first of which is devoted to laboratory instruction and practical classes (including those for the Diploma); the second being devoted to advanced study and research. The courses may be taken at any time, and students are allowed to work daily in the laboratories.

University of Leeds.—The University grants a Diploma in Public Health, and every facility is afforded for training in Sanitary Science and State Medicine. The examination, which is held twice in each year—namely, in June and December—is in two parts, and is written, oral, and practical. Candidates must pass in Part I. before being admitted to Part II. Instruction in Entomology and Meteorology is given in the first term, and in Sanitary Chemistry and Bacteriology in the second and third terms. Practical work under arrangement with the Leeds City Council. Prospectus can be obtained from the Academic Sub-Dean of the Medical School.

University of Bristol.—Diploma in Public Health. Candidates must be at least 23 years of age, shall be fully registered medical practitioners of not less than two years' standing as such, and shall have passed the examination prescribed by regulations, which can be obtained from the Registrar upon application.

University of Wales.—Candidates for the Diploma in Public Health, the curriculum for which extends over a period of not less than twelve calendar months subsequent to the attainment of a registrable qualification, must produce evidence of having attended for not less than five months at the Welsh National School of Medicine or at an institution approved by the Court, practical instruction in Bacteriology and Parasitology, Chemistry and Physics, and Meteorology and Climatology in relation to Public Health. Candidates must also satisfy the examiners that they have received instruction approved by the University in the Principles of Public Health and Sanitation, Epidemiology and Vital Statistics, Sanitary Law and Administration, and Sanitary Construction and Planning. The candidate must also produce evidence that he has attended for three months on the clinical practice of a hospital for infectious diseases containing not less than 100 beds, and has received therein instruction in the methods of administration, and that he has for a period of not less than six months been engaged in acquiring a practical knowledge of the duties, routine and special, of a public health administration under the supervision of a medical officer of health. The examination for the diploma is divided into two parts, Part I. and Part II., each of which extends over not less than two days. A candidate must pass in all the subjects of Part I. before being admitted to Part II. of the examination. In Part I., and also in Part II., a candidate must pass in all the specified subjects at one time. Part I. of the examination is practical, written and oral, and comprises Bacteriology and Parasitology (including Medical Entomology); Chemistry and Physics, and Meteorology and Climatology in relation to Public Health. Candidates may not be admitted to Part I. of the examination until they have been certified as having pursued the prescribed courses of instruction in the subjects thereof. Part II. of the examination, which is written and oral, comprises: Hygiene and Sanitation (including Sanitary Construction); Epidemiology and Infectious Diseases; Sanitary Law and Vital Statistics; Public Health Administration. No candidate can be admitted to Part II. of the examination until after the lapse of not less than two years from the date of his obtaining a registrable qualification in Medicine, Surgery, and Midwifery, which qualification must be registered before admission to Part II. of the examination. An examination in each part will be held annually. The examination in Part I. will be held in June, that in Part II. in October. Full information from the Registrar of the University, University Registry, Cathays Park, Cardiff, not later than May 15th for the examination in Part I. and not later than Sept. 1st for the examination in Part II.

University of Edinburgh.—Candidates for the Diploma in Public Health must be graduates in medicine and surgery of the University, or hold corresponding degrees or registrable medical qualifications which must be registered before admission to examination. The course is divided into two parts for which examinations are held twice yearly, in March and July for Part I., and in October and March for Part II. In each part the candidate must pass in all the specified subjects at one examination. Candidates are not admitted to Part II. until they have passed Part I., nor until after the lapse of not less than two years from the date of obtaining a registrable medical qualification. The subjects of the examination are: Part I. (written, oral, and practical), Bacteriology; Medical Entomology and Parasitology; Chemistry, Physics, Meteorology, and Climatology. Part II. (written, oral, and practical), Hygiene, Sanitation, and Sanitary Construction; Epidemiology and Infectious Diseases; Sanitary Law and Vital Statistics; Public Health Administration. There is also included practical examinations in Infectious Diseases, Food Inspection, and Inspection of Premises. The course, which extends over a period of 12 calendar months, begins in October, and provision is made by the University for instruction in all the subjects. Detailed particulars may be obtained from the Dean of the Faculty of Medicine.

University of Aberdeen.—Every candidate for the Diploma in Public Health must be a graduate in medicine of the University of Aberdeen, or of any other University whose medical degrees are recognised as qualifying for registration by the General Medical Council of the United Kingdom. No candidate will be admitted to the Final Part of the Examination for the Diploma until after the lapse of not less than two years from the date of his obtaining a registrable qualification in Medicine, which qualification shall have been registered before such admission. The whole of the prescribed curriculum of study must be undertaken after the candidate has obtained a registrable qualification in medicine, and shall extend over not less than twelve calendar months. At least one academic term must be spent at the University of Aberdeen. Every candidate shall produce evidence of having complied with the following requirements in respect of study and training:—1. Practical instruction in the following subjects within a laboratory or laboratories approved by the University: (*a*) Bacteriology and Parasitology (including Medical Entomology), in relation to diseases of man and diseases of lower animals transmissible to man—at least 180 hours, of which not less than 150 shall be occupied in practical laboratory work; (*b*) Chemistry and Physics, in relation to Public Health—at least 90 hours, of which not less than 70 shall be occupied in practical laboratory work; (*c*) Meteorology and Climatology, in relation to Public Health—at least 10 hours; such instruction to extend over not less than five months or two academic terms. 2. A course or courses of instruction extending over not less than 80 hours dealing with: (*a*) The Principles of Public Health and Sanitation—30 hours; (*b*) Epidemiology and Vital Statistics—20 hours; (*c*) Sanitary Law and Administration (including Public Medical Services)—20 hours; (*d*) Sanitary Construction and Planning—10 hours; such course or courses to be given at an institution or by a teacher or teachers approved by the University. 3. Practical instruction, clinical and administrative, within a recognised hospital for general infectious diseases; such instruction to extend over three months, and to include 30 daily attendances of not less than two hours in each week. 4. Practical instruction and experience, during not less than six months (including attendance of at least three hours on each of sixty working days) in the duties, routine and special, of public health administration, under the supervision of a medical officer of health, who shall certify that the candidate has received from this officer or other competent medical officer, practical instruction in these duties, and also in those relating to: (*a*) Maternity and Child Welfare Service; (*b*) Health Service for Children of School Age; (*c*) Venereal Diseases Service; (*d*) Tuberculosis Service; (*e*) Industrial Hygiene; (*f*) Inspection and Control of Food, including meat and milk. The medical officers of health recognised for this purpose by the General Medical Council are: (*a*) a medical officer of health who devotes his whole time to public health work; or (*b*) the medical officer of health of a sanitary area having a population of not less than 50,000; or (*c*) in Ireland, the medical superintendent officer of health of a county or county borough having a population of not less than 50,000. The examination for the diploma is divided into two parts, each of which extends over not less than three days.

University of Glasgow.—Degree of B.Sc. in Public Health.—Candidates must be graduates in Medicine of a University of the United Kingdom, or of some other University recognised for the purpose by the University Court. Candidates must produce evidence (1) that, after they have obtained a registrable Degree in Medicine, a period of not less than two years has elapsed; (2) that, after they have obtained a registrable degree in Medicine, they have, during a period of not less than 21 calendar months, pursued the course of work and instruction prescribed, and have satisfied the examiners in the prescribed examinations. There are two examinations. Part I. includes the following subjects: (i) Bacteriology and Parasitology (including Medical Entomology); (ii) Chemistry and Physics in relation to Public Health; (iii) Meteorology and Climatology in relation to Public Health; (iv) Higher Chemistry in relation to Public Health; (v) Physics and Geology. A candidate must pass in the subjects marked (i), (ii), and (iii) of Part I. at one examination. Part II. includes the following subjects: (vi) Hygiene and Sanitation (including Sanitary construction); (vii) Epidemiology and Infectious Diseases; (viii) Sanitary Law and Vital Statistics; (ix) Public Health Administration; (x) Applied Hygiene. The examination for Part II. includes practical examinations in Infectious Diseases; Food Inspection; Inspection of Premises, such as dwellings, factories, workshops, schools, and the like. The examination in Applied Hygiene may be on a selected subject professed by the candidate. A candidate must pass in the subjects marked (vi), (vii), (viii), and (ix) of Part II. at one examination. *Diploma in Public Health (D.P.H.).*—Candidates for this Diploma must be legally qualified medical practitioners who are matriculated students of the University. A period of not less than two years must elapse between the attainment by the candidate of a registrable medical qualification, and his admission to the final examination (Part II.) for the Diploma. The candidate must, during a period of not less than 12 calendar months, subsequent to his attainment of a registrable medical qualification, pursue the course of work and instruction prescribed, and pass the prescribed examinations. The examination, which is both written and oral, is divided into two parts, Part I. and Part II., each of which extends over not less than two days. No candidate is admitted to either part of the examination until he has completed the prescribed courses of instruction in the subjects of that part. No candidate is admitted to Part II. until he has passed in all the subjects of Part I., nor until after the lapse of not less than two years from the date of his obtaining a registrable medical qualification, nor unless he presents a certificate showing that his name and qualification have been duly registered in the Medical Register. Part I. includes: (i) Bacteriology and Parasitology (including Medical Entomology); (ii) Chemistry and Physics in relation to Public Health; (iii) Meteorology and Climatology in relation to Public Health. A candidate must pass in all the subjects at one examination. Part II. includes: (iv) Hygiene and Sanitation (including Sanitary Construction); (v) Epidemiology and Infectious Diseases; (vi) Sanitary Law and Vital Statistics; (vii) Public Health Administration. A candidate must pass in all the subjects at one examination. The examination for Part II. includes practical examinations in Infectious Diseases; Food Inspection; Inspection of Premises, such as dwellings, factories, workshops, schools, and the like.

University of St. Andrews.—The Diploma in Public Health is open to those who hold a registered medical qualification of the United Kingdom. The examination is in two parts. (1) (*a*) Bacteriology and Parasitology; (*b*) Chemistry and Physics; (*c*) Meteorology and Climatology. (2) Public Health and Sanitation, Epidemiology and Vital Statistics, Sanitary Law and Administration, and Sanitary Construction and Planning. Before admission to the first examination the candidate must have held his medical qualification for one year, and before admission to the second examination for two years. Graduates in Medicine of the University of St. Andrews may take part or all of the qualifying classes in any University of the United Kingdom, or in any Indian, Colonial, or Foreign University or medical school recognised by the University Court, but holders of other registered medical qualifications must spend at least eight out of the 12 months' curriculum in St. Andrews University. A complete course is given in the Conjoint Medical School, Dundee. The examination fee for each division is £5 5*s*.

University of Dublin (Trinity College).—The Diploma in Public Health is conferred, after examination, under the following conditions. The candidate must be a registered medical practitioner and have obtained a registrable qualification at least two years before the second part of the examination. The candidate must have completed, subsequently to obtaining a registrable qualification, five months' practical instruction in a chemical and bacteriological laboratory, or laboratories, approved by the University, must have received instruction in the following subjects: the principles of public health and sanitation, epidemiology and vital statistics, sanitary law and administration (including public medical services), sanitary construction and planning; must have studied practically, outdoor sanitary work for six months under an approved officer of health, and must have attended for three months at a fever hospital where opportunities are afforded for the study of methods of administration. A special prospectus may be obtained by application to the Registrar of the School of Physic, Trinity College, Dublin.

*National University of Ireland.**—At this University there is a Diploma in Public Health, a B.Sc. in Public Health, and a D.Sc. in Public Health.

University of Belfast.—A Diploma in Public Health is given by examination. Every candidate must produce evidence that, after obtaining a registrable qualification, he has during six months received practical instruction in an approved laboratory in which Chemistry, Bacteriology, and the Pathology of the diseases of animals transmissible to man are taught. After obtaining a registrable qualification every candidate must produce evidence that he has attended during three months the practice of a hospital for infectious diseases at which opportunities are afforded for the study of methods of administration. The examination must have extended over not less than four days, one of which shall have been devoted to practical work in a laboratory, and one to practical examination in, and reporting on, subjects which fall within the special outdoor duties of a medical officer of health. The first part of the examination will have reference to the general principles of Sanitary Science and the second part to State Medicine and to the applications of Pathology and Sanitary Science. The examination in both parts is held twice a year, in March and June.

Royal College of Physicians of Edinburgh, Royal College of Surgeons of Edinburgh, Royal Faculty of Physicians and Surgeons of Glasgow.—All candidates for the Diploma in Public Health must have a qualification which has been registered under the Medical Acts. Candidates must have attended not less than four calendar months' practical instruction in Chemistry and Physics (90 hours), Bacteriology and Parasitology (180 hours), and Meteorology and Climatology (60 hours) in a recognised laboratory or laboratories, must have studied outdoor sanitary work for six months under a medical officer of health or other sanitary officer; and must give evidence of attendance for three months at the practice of a Hospital for Infectious Diseases, at which he has received instruction in the methods of administration. The examination consists of two parts, and candidates may enter for both at one period or for either separately. The First Part includes (*a*) Laboratory Work (Chemistry and Bacteriology), (*b*) Physics and Meteorology; and the Second Examination embraces (*a*) Report on Premises visited, (*b*) Examination at Fever Hospital, (*c*) Examination at Public Abattoir, (*d*) Written and Oral Examinations on Epidemiology and Endemiology, (*e*) Vital Statistics and Sanitary Law, and (*f*) Practical Sanitation. The fee is 12 guineas for both examinations, or 6 guineas for either of them. A fee of 3 guineas is payable by rejected candidates for either examination. The examination is held twice yearly, in May in Glasgow, and October in Edinburgh. The published regulations provide detailed synopses of the subjects of examination. *The curriculum and examination have been adjusted fully to meet the requirements of the regulations of the General Medical Council which came into force on Jan. 1st, 1924.* Candidates applying for Regulations should state date of commencement of curriculum. The Registrar for Edinburgh is Mr. D. L. Eadie, 49, Lauriston-place, and for Glasgow Mr. Walter Hurst, 242, St. Vincent-street.

Royal College of Physicians of Ireland and Royal College of Surgeons in Ireland.—Every candidate for the Diploma in Public Health must observe the following rules: 1. A period of not less than two years shall elapse between the attainment by a candidate of a registrable qualification in Medicine, Surgery, and Midwifery, and his admission to the Final Examination for a Diploma in Public Health. 2. The curriculum for a Diploma in Public Health shall extend over a period of not less than 12 calendar months subsequent to the attainment of a registrable qualification. 3. Every candidate shall produce evidence of having attended, during a period of not less than five months, at an institution approved by the Licensing Body granting the Diploma, practical instruction in—(*a*) Bacteriology and Parasitology (including Medical Entomology), especially in their relation to diseases of man, and to those diseases of the lower animals which are transmissible to man; (b) Chemistry and Physics in relation to Public Health; (c) Meteorology and Climatology in relation to Public Health. At least 180 hours must be devoted to Course (a), of which not less than 150 hours shall be occupied in practical Laboratory work. At least 90 hours must be devoted to Course (b), of which not less than 70 hours shall be occupied in practical Laboratory work. At least 10 hours must be devoted to Course (c). 4. Evidence of having received, during not less than 80 hours, at an institution or from teachers approved by the Licensing Body granting the Diploma, instruction in the following subjects: (a) The Principles of Public Health and Sanitation; (b) Epidemiology and Vital Statistics; (c) Sanitary Law and Administration (including Public Medical Services); (d) Sanitary Construction and Planning. 5. Evidence that he has attended for three months on the clinical practice of a recognised Hospital for Infectious Diseases. 6. Evidence that he has, during a period of not less than six months, been engaged in acquiring a practical knowledge of the duties, routine and special, of Public Health Administration under the supervision of a Medical Officer of Health. The examination for the Diploma is divided into two parts. The examination for Part I. includes Bacteriology and Parasitology (with Medical Entomology); Chemistry and Physics, and Meteorology and Climatology, in relation to Public Health. The examination for Part II. includes Hygiene and Sanitation (with Sanitary Construction); Epidemiology and Infectious Diseases; Sanitary Law and Vital Statistics; Public Health Administration. The examination, which is written and oral, includes practical examinations in Infectious Diseases; Food Inspection; Inspection of Premises—dwellings, factories, workshops, and schools.

---

* No returns.

DENTAL SURGERY.

REGISTRATION on the Medical Register entitles a practitioner to practise as a dentist, although he cannot register as such without degree or licence in dentistry; but few dental appointments at general or special hospitals or dispensaries are available save to those with a special diploma, and until registered on the Dentist Register, no dental work under the Additional Benefit Scheme of the National Health Insurance Act can be undertaken.

The Examining Bodies in Dentistry which grant degrees and diplomas in the subject are as follows: Royal College of Surgeons of England, Royal College of Surgeons, Edinburgh, Royal Faculty of Physicians and Surgeons of Glasgow, Royal College of Surgeons in Ireland, and the following Universities: Birmingham, Bristol, Durham, Leeds, Liverpool, London, Manchester, Sheffield, St. Andrews, Dublin (Trinity College), Queen's University of Belfast, and the National University of Ireland. The respective requirements of the various examining bodies in dentistry are very similar, being designed to meet the requirements of the General Medical Council, but the examinations vary in stringency, and each school has its rules for matriculation and exemption, and its scale of fees. The student should apply to the secretaries of the various Conjoint Boards or to the Deans of the medical faculties or medical schools for a syllabus.

TEACHING INSTITUTIONS IN DENTISTRY: LONDON.

Royal Dental Hospital of London, School of Dental Surgery. Leicester-square.—A school of the University of London. Women are admitted as students and are eligible for all hospital appointments and school prizes. The school provides the special dental education required by the Royal College of Surgeons for the Licence in Dental Surgery. The general part of the curriculum may be taken at any general hospital. The hospital is open from 9 A.M. to 5 P.M., there being one staff for the morning and another for the afternoon of each day. Pupils are received for the training in dental mechanics recognised by the curriculum. The instructors at the commencement of each session give a course of lectures on Operative Dental Surgery. The five house surgeoncies are held for six months each and are open to all qualified students. The lecturers, in addition to their lectures, give special demonstrations on the Microscopy of Dental Anatomy and Dental Surgery. The lecturer on Dental Mechanics also gives practical demonstrations in the laboratory. There is an Entrance Scholarship in Chemistry and Physics of the value of £25. One Entrance Scholarship in Dental Mechanics and Metallurgy, value £25, open to pupils of the Hospital only. Prizes and certificates are awarded by the lecturers for the best examinations in the subjects of their respective courses at the end of the summer and winter sessions. For full information as to scholarships and prizes, and other matters connected with the course, application should be made to the Dean.

University College Hospital Dental School, corner of Great Portland and Devonshire-streets, W.—This Hospital and School has recently been thoroughly reorganised, and is now fully equipped with all the most modern appliances. Students are entered as students of University College Hospital, and, as such, attend the classes of Anatomy and Physiology in University College, which is a few minutes' walk from the Dental Department in Great Portland-street, hitherto known as the *National Dental Hospital,* the first Dental School to admit Women Students. Practical courses to comply with the R.C.S. curriculum are held. Clinical Lectures and Demonstrations are given, and each student on entering passes through a preliminary course under a demonstrator. A prospectus containing full information as to lectures, fees, and prizes may be had on application to the Sub-Dean for Dental Students, who attends at University College Hospital Medical School, University street, W.C.1, on Wednesday mornings from 9.30 to 10.30, and at other times by appointment.

Guy's Hospital Dental School.—The work of the Dental Department begins daily at 9 A.M. both in the extraction rooms and in the conservation room. The Extraction Rooms: There is ample accommodation for both general and local anæsthetic extractions, together with waiting- and retiring-rooms. Patients are admitted between 8.45 and 9.30 A.M., and are seen by the dental surgeon for the day, the staff demonstrators, the dental house surgeons, and the dressers. The Conservation Room is open from 9 A.M. till 5 P.M. It affords accommodation for about 100 dental chairs, with the necessary equipment of the most modern type for the use of the Dressers, who, under the supervision of the Staff, perform the various operations of Dental Surgery. There is a separate room for denture patients affording accommodation for 15 chairs and a separate department for children with accommodation for 20 chairs. The Members of the staff attend every morning and afternoon to give demonstrations and otherwise assist students in their work in the Conservation Room and Prosthetic Laboratory. The Probationers' Laboratory is supervised by three of the staff demonstrators, and instruction is given in operative dentistry on a "mannikin" to students during their first three months of clinical study. Students in Dental Prosthetics are received, and a graded, systematic, and full course of instruction, extending over two years, is carried out under the supervision of the Director of the Prosthetic Laboratory, assisted by two demonstrators, a house surgeon, and five mechanics.

Dental students have the opportunity of attending at this hospital the whole course of instruction required by the examining board for the B.D.S. Lond. or L.D.S. Eng.—viz., the complete course in dental prosthetics, the special lectures and practice of the Dental Department, and the general lectures and practice of the Medical School. The fees for these two courses may be paid separately or together, or they may be combined with the fees required to be paid for the course for a medical diploma. Students who enter for a medical as well as a dental diploma are allowed to pursue their study of Dentistry during any period of their medical course most convenient to themselves without further charge.

Twelve house surgeons, 20 assistant house surgeons, and four student demonstrators of Dental Histology are appointed annually. The following appointments are held by students: Full surgeon's dresser, assistant surgeon's dresser, dresser in the children's department, casualty dresser, clerk to the anæsthetist, dresser in the gas extraction and local anæsthetic extraction rooms, and probationary dresser. For particulars as to scholarships and prizes, as well as all information, application should be made to the Dean of the Medical School, Guy's Hospital, London Bridge, S.E. 1.

King's College Hospital.—The Dental School is part of the Medical School of King's College Hospital, and was opened in November, 1923. The Dental Out-patient Department of the Hospital is used for the performance of dental extractions. A large Conservation Room with provision for 40 dental chairs has been equipped. Smaller rooms are used for clinical teaching and administrative requirements, and a specially equipped laboratory for training in the art of dental mechanics. An X ray apparatus has been installed for special use in dental skiagraphy. A museum containing a large number of specimens illustrating oral, buccal, dental, and other diseases is available for teaching purposes. The library, lecture theatre, lecture rooms, common rooms, and the refreshment room are all available for the use of students. Courses of study, including practical work, are provided for the degree of Bachelor of Dental Surgery of the University of London, and for the Diploma in Dental Surgery of the Royal College of Surgeons of England. Special arrangements are made for those students who wish to take a medical degree or qualification in addition to a degree or diploma in Dental Surgery.

The following salaried appointments are open to qualified members of the School: Registrar, Resident House Surgeon, Non-Resident House Surgeon, and Tutor in Dental Mechanics.

Full particulars of the Dental School may be obtained on application to the Dean, or to the Secretary of the Medical School, King's College Hospital, Denmark Hill, London, S.E.

London Hospital.—This school is a part of the London Hospital and Medical College, and is fully equipped on the most modern lines and with the latest appliances. It provides a complete curriculum in all subjects for the B.D.S. Degree and for the L.D.S. Diploma, and is admirably adapted for the purpose of teaching. The Conservation Room is well lighted and ventilated and fitted with pump chairs of the latest pattern; the fountain spittoons at many of the chairs have been specially designed. Each spittoon has attached to it a saliva ejector, hot and cold water, compressed air, gas and electric current, also a swing bracket to carry the students' cabinet. Electric sterilisers are supplied in each department and motor engines where required. The School possesses, in addition to the Theatres, Laboratories, and Museums in the College, a special Museum of Dental Anatomy and Surgery, Operative Dentistry, Prosthetic and Extraction Rooms, and Laboratories for Practical Metallurgy and Prosthesis. A systematic course of instruction is arranged for pupils. The up-to-date Laboratory contains every modern apparatus and is in charge of a skilled curator and his assistants. Connected with the Medical College and Dental School are a Library, Athenæum, Clubs' Union, Dining Hall with moderate tariff, Students' Hostel, and an Athletic Ground. For full particulars as to Scholarships and Prizes, fees and course of study advised, apply to the Dean of the Medical School.

London (Royal Free Hospital) School of Medicine for Women.—Full courses are arranged for women students in conjunction with the Royal Dental Hospital, Leicester-square, for the study of dentistry; and in preparation for the B.D.S. Degree of the University of London and the Licence in Dental Surgery of the Royal College of Surgeons of England, at the London (Royal Free Hospital) School of Medicine for Women.

TEACHING INSTITUTIONS OUTSIDE LONDON.

Birmingham Dental Hospital, Great Charles-street.—Dean: Cyril Howkins, C.B.E., D.S.O., M.R.C.S., L.D.S. The Dental Hospital has accommodation for 100 students. The equipment is in accordance with the most modern requirements for the efficient teaching and practice of Dental Surgery, including Radiology and Ultra-Violet Ray Therapy and a new department for Practical Pathology and Bacteriology. The operations performed annually average 35,000, including gold and other fillings, crowns, bridges, porcelain inlays, and injections for block and infiltration anæsthesia. The orthodontic department is one of the foremost in the country. The Prosthetic and Mechanical Department is large and well lighted and under a highly skilled instructor who is always present. Application for information as to fees and scholarships must be sent to the Dean of the Medical Faculty, Birmingham University, or the Dean of the Dental Hospital, Birmingham.

Leeds University School of Dentistry.—The School of Dentistry is adequately equipped to provide for the complete training of the dental student. It forms a part of the Leeds School of Medicine whilst the instruction in clinical and mechanical dentistry is carried out in the Dental Hospital. The School is now in occupation of a spacious new building especially designed to the requirements of modern dental teaching. The School is also the dental department of the General Infirmary, and its close association with the work of that institution ensures an adequate supply of clinical material, and enables a fuller insight into the position dental surgery holds in relation to general medicine and surgery, especially with regard to the major diseases and injuries of the head and neck. The courses of study are mainly designed to meet the requirements of the B.Ch.D. and L.D.S. Leeds, but every opportunity is afforded to students preparing for the degrees or diplomas of other licensing bodies. Full-time demonstrators give the instruction in clinical dental surgery, prosthetic dentistry, and mechanics, which is carried out under the supervision and direction of members of the Honorary Staff, two of whom are in attendance each day. Special facilities are provided for instruction in Orthodontia, Dental Radiography, Local and General Anæsthetics. Prizes are offered for competition to pupils and students in their respective years of study. Communications should be addressed to the Warden, School of Dentistry, Leeds, from whom a prospectus may be obtained.

Dental Hospital of Manchester.—This hospital is in association for teaching purposes with the University of Manchester and the Royal Infirmary, and is in the centre of a very large population. Courses of study are provided to meet the requirements of the various examining bodies, including those of the University of Manchester for the qualifications L.D.S. and B.D.S., and the L.D.S. of the Royal College of Surgeons of England. Clinical instruction is given in Dental Prosthetics, Operative Dentistry, Diagnosis and Extraction, Orthodontics, Dental Surgery, Radiography, and Anæsthetics by specially appointed Clinical Teachers.

All the courses of instruction are open to women students. Copies of the Prospectus will be forwarded on application to Mr. J. Hilditch Mathews, Dean.

Newcastle-upon-Tyne Dental Hospital and School.—This hospital is centrally situated (within five minutes of the various colleges, infirmary, and railway station);

the rooms are well lighted and thoroughly equipped for carrying on the work. Dental surgeons and an anæsthetist attend each morning. A tutorial dental surgeon and a prosthetic tutor are also in attendance. Medals and Certificates of Merit are granted to students showing certain standards of proficiency in the various classes at the Dental School. The prospectus of the Dental Hospital and School, containing full information, may be obtained from Mr. James Coltman, 13, Ellison-place, Newcastle-upon-Tyne, Dean.

Devon and Exeter Dental Hospital, 24, Southernhay West, Exeter.—The hospital is open on Mondays, Tuesdays, Wednesdays, Thursdays, Fridays, and Saturdays, and patients are admitted between the hours of 9.30 and 11 A.M. Students attend the practice of the hospital under the control of the medical officers.

SCOTTISH TEACHING INSTITUTIONS.

The Incorporated Edinburgh Dental Hospital and School.—The Edinburgh Dental Hospital and School is located in spacious and well-equipped buildings at 30, 31, and 32, Chambers-street, and offers special advantages to dental students. A large and important extension of the existing buildings has now been opened. The General Courses required for the Dental Diploma may be taken in the Medical School of the Royal Colleges of Physicians and Surgeons or in the University schools. The general hospital attendance and clinical instruction are taken at the Royal Infirmary. The University, Medical Schools, and Royal Infirmary are within three minutes' walk of the Dental Hospital. The special courses are taken in the hospital. The Dental Hospital practice, extending over two years, affords a student ample opportunity for a full acquaintance with every branch of dentistry. The hospital admits a limited number of indentured pupils. They receive their instruction in Mechanical Dentistry concurrently with the general and special courses. A premium of 60 guineas is payable with each such pupil. The practice and lectures of the hospital are recognised by, and qualify for, all the Licensing Boards. Those students who desire to take a Medical and Surgical Diploma in addition to the L.D.S. have in this school admirable facilities for so doing. The triple qualification of the Royal College of Physicians and Surgeons of Edinburgh and the Royal Faculty of Physicians and Surgeons of Glasgow is recommended. The Higher Dental Diploma (H.D.D.) of the Royal College of Surgeons affords an opportunity of obtaining a higher qualification subsequent to registration. The Prospectus, with full information, may be obtained by application to the Dean or the Assistant Secretary.

Incorporated Glasgow Dental Hospital, 158, Renfrew-street and 15, Dalhousie-street, Glasgow.—The School is open to Men and Women Students, and Lectures are given on Dental Surgery, Operative Dental Surgery, Orthodontia, Dental Anatomy and Physiology, Dental Histology, Dental Mechanics, Crown and Bridge work, Dental Metallurgy, Dental Bacteriology, Radiology, Anæsthetics, and Dental Materia Medica. Lectures on general subjects required for Dentistry may be taken at the University or at one of the extra-mural schools where special provision is made for Dental Students. A new mechanical laboratory with bench accommodation for 60 pupils and fully equipped with the most modern appliances for teaching practical dental mechanics has recently been added. Full information may be had on application to the Dean.

Glasgow Royal Infirmary (Dental Department).—The following course in the curriculum can be taken at St. Mungo's College: Anatomy, six months; Practical Anatomy, nine months; Physiology, six months; Chemistry, six months; Practical Chemistry, three months; Surgery, six months; Medicine, six months; Materia Medica, three months; Dental Surgery, six months, and attendance for two years on the dental department of the hospital. Clinical Medicine (three months) and Clinical Surgery (six months) are taken at the Royal Infirmary.

IRELAND.

Incorporated Dental Hospital of Ireland, Lincoln-place, Dublin.—All Dental Students who have passed their Second Dental Examination in the Royal College of Surgeons in Ireland (or an equivalent examination or examinations) are admissible to the Clinical Instruction of the Hospital. In addition to Clinical Instruction and Special Demonstrations, courses of lectures are given at the hospital on Dental Surgery and Pathology, Mechanical Dentistry, the Administration of Anæsthetics, Orthodontia, Dental Anatomy, and Dental Materia Medica, and instruction in Anæsthetics. The course in practical Dental Mechanics can be taken in the Hospital Laboratory. Further particulars can be obtained from the Dean.

PRISON MEDICAL SERVICE.

CANDIDATES for the Prison Medical Service are approved by the Secretary of State for the Home Department on the recommendation of the Prison Commissioners. Preference is always given to candidates who have experience of lunacy. Application for employment may be made on a special form, which can be obtained from the Secretary, Prison Commission, Home Office, London, S.W. In the smaller prisons the medical officership is part-time, and is usually filled by practitioners in the locality, preference being given to those who have special experience of lunacy. In the large prisons the medical staff must devote their whole time to the Service. In the case of whole-time service, the appointment is in the first instance to the post of Medical Officer, Class II., and from the seniors of this rank the Medical Officers, Class I., are selected as vacancies occur. The pay of the whole-time prison medical staff is as follows: Medical Officer, Class II., £350, rising by annual increments of £20 to £600, making the pay at present with bonus £485 8*s.* to £776 7*s.*; Medical Officer, Class I., £650, rising by annual increments of £25 to £800, plus bonus, making the pay £837 5*s.* to £995 11*s.* Unfurnished quarters are provided or an allowance in lieu is made. Study-leave is granted annually to two of the whole-time Medical Officers. There are 12 full-time medical officers of Class I. and 15 Class II., and 23 part-time medical officers. The number of vacancies is never large and promotion is slow.

THE ELIZABETH GARRETT ANDERSON HOSPITAL.—Application for a Charter of Incorporation has been made by the Marchioness of Dufferin and Ava and others on behalf of the Elizabeth Garrett Anderson Hospital.

INTERNATIONAL MEDICAL POST-GRADUATE COURSES IN BERLIN.—In connexion with the Medical Faculty of Berlin post-graduate courses are held by the Lecturers' Association for Medical Continuation Courses and the Kaiserin Friedrich-Haus. The regular courses last from two to four weeks; other courses for those wishing to act as resident assistants in clinics, hospitals, and laboratories, lasting two to three months and longer, are arranged under systematic supervision. Courses will also be held next month as follows: Oct. 1st to 13th, General Survey of Medical Progress with Special Reference to Pulmonary Diseases; Oct. 8th to 20th, Nose, Throat, and Ear Course for Specialists; Oct. 15th to 27th, Pediatry. There will also be a course on New Methods of Diagnosis and Therapy, with practical clinical studies and exercises in the City Hospital, Friedrichshain, and its laboratories, as well as single courses in special fields of medical science, including practical work. The courses are held in German, but some of the professors speak English, French, and Spanish. Further information and details as to lodgings and so forth can be obtained from the Kaiserin Friedrich-Haus, Luisenplatz 2–4, Berlin, N.W. 6.

PUBLIC AUTHORITIES AND RESEARCH.*

BY JAMES M. BEATTIE, M.D. EDIN.,
PROFESSOR OF BACTERIOLOGY IN THE UNIVERSITY OF LIVERPOOL.

AT present there are a few public authorities which encourage research to a limited extent, but the great bulk of them do practically nothing, and research is largely financed by private individuals, or by universities and colleges which can ill afford the money. I do not forget the national effort in our Medical Research Council and what is done under the direction of the Ministry of Health and the Ministry of Agriculture. But the work of these ministries is restricted and greatly hindered by want of funds. Very often, before any substantial results are obtained, it is interrupted because the money voted is exhausted. The Medical Research Council also is hampered by financial considerations, and one sometimes wonders whether those under whose direction the work is done have really an absolutely free hand. Large organisations of this kind, whether supported by Government or by private associations with large committees, have of necessity to produce reports at stated intervals, and these reports must contain results of work done. Not uncommonly that work is unfinished and not thoroughly controlled; the investigators fully realise this, but the committee has to be satisfied, and the subscribers expect results for the money they have given.

Danger of Directing Research.

I think these large organisations have other decided disadvantages. It is a necessity that there should be someone directing the different branches of the research carried on. He may be a very able man, and he usually is. He forms his plan of investigation, and his workers having that plan before them pursue lines which lead to the central point in that plan. There is the one brain which dominates and the investigator must not follow side-tracks. Of all new information which comes to him during the course of his investigation, only that information can be accepted which seems to help him along the special track which has been chosen, and if the track is wrong then a new track has to be found, and months, and even years, of research have merely led to an impassable wall.

I do not underrate the value of such work—barren though the final result may be—but what I do deprecate is that by the establishment of central institutes there are only a limited number of tracks blazed. There are numbers of men who, given an opportunity, would see other roads, so that instead of one man planning a special line of attack there would be a dozen men possibly planning a dozen lines, with an increased probability of success. For this reason, but not for this alone, I would urge that research centres should be as widespread as possible.

Disadvantages of Research Institutes.

The research institute is generally divorced from the hospital, and it is almost inevitable that the clinical side of disease in the human subject should be ignored in favour of animal experiment. If progress is to be made it is, to my mind, essential that the hospital and the research department should be closely associated, and the research worker should, by preference, be a man with experience as a clinician. But in practice we find our research institutes staffed by young men—very often brilliant young men—who have just qualified and whose real experience of disease is extremely limited. Is it to be wondered at that much of what they do has little or no bearing on the problems of the everyday practice, and that the laboratory worker is becoming more and more a pure scientist, separated entirely from the clinician? Let me say, in passing, that the laboratory worker is not altogether to blame, for many clinicians show no desire to aid the pathologist or to give him any facilities for keeping in touch with the sick man. The research institute, I believe, helps in this separation; certainly there would be less tendency towards it if the research laboratory were intimately associated with a hospital, as most of our university laboratories are.

Again, it may be asked, is the money expended to the best advantage? I am not here concerned with places like the Rockefeller Institute, which have a hospital attached and where there is neither financial restriction nor an obligation on the research worker to show cause for his existence, but I refer rather to the ordinary research institute with its elaborate buildings and equipment. The administrative expenses are usually very heavy. Much of this expense could be avoided—or, at any rate, the money be more advantageously spent—if the workers were distributed over the various laboratories now in existence, and these research centres spread widely over the country.

Organisation versus Initiative.

We all rejoice in the present great national appeal for cancer research, but how will the money be used? A great research worker said to me a few weeks ago: "This appeal has killed cancer research."—"Why?" I asked. "Because we are out for something big," he answered, "something that will appeal to the people. The man who has been working quietly and steadily in his own laboratory—hampered, it is true, by want of funds—is likely to be absorbed into an institute; his initiative will be crushed because he has to work along a plan made by a director, and money which could be used to finance these individual workers will go to the ere[illegible] cancer hospitals—and to [illegible] This may be a pessimistic view, but it is one which demands our earnest consideration. I am still a believer in the individual worker, financed properly—one who uses his own brains, thinks out his own problems, and gets himself in touch with his fellow workers in the same field, and discusses with them his ideas. Team-work has been tried, but I venture the opinion that most men who have had experience of it are looking forward to the funeral rather than to the festival.

A contemporary writer speaks of the loss of efficiency consequent on "subjecting policy to the constant censorship of uninformed critics" as one of the evils of democratic government. This censorship and this criticism in research is one of the greatest evils of the committee system of directing it.

We have seen some evidence of this in the recent reports on cancer research. For instance, the very fact that public discussion of the lead treatment of cancer has been necessary at this stage is because the whole research on cancer has come under the auspices of a Committee which must publish its results in order to stimulate the public to raise more money. I say that such public discussion has done a great deal of harm to the progress of the research.

A Better Way.

If the local authorities will agree to give facilities in their various hospitals and institutions and the universities and colleges will place their laboratories and their trained staff at the disposal of these workers, then the thing, administratively, is accomplished. The administrative expenses would be small, as the laboratories at present in existence at the universities could be used and the head of the university department would supervise the work. Thus, there would be no expenses for building, and very little for apparatus and materials, and the supervising head would, I have little doubt, in most cases, if not in all, accept the responsibility without extra payment. The main payments would be to the research workers, and these should be paid by the local authorities. These research workers are, in my opinion, as much a necessity in the hospitals of the local authorities as the resident medical officers, but they must be men who have been trained, and they should have, at least, an equal status, financial and otherwise, with the senior resident medical officers. They must be closely in touch with the clinical work of the hospital and should have all the advantages of the senior medical officers, with whom they must be in constant collaboration.

---

* Abridged from a presidential address delivered before the Section of Bacteriology, Pathology, and Biochemistry of the Royal Institute of Public Health at Dublin on August 15th.

Let me here say that I do not mean by research the ordinary routine examinations which so often constitute the work of the hospital pathologist, nor do I mean the ordinary class of work—often designated research—which is so often produced by the man whose sole object is to get a higher degree. I mean a real investigation which has for its object the solution of a problem which will throw some light on the cause or treatment of disease.

Collaboration of Universities.

Let me outline briefly what I consider should be done. In the first instance, that local authorities in the neighbourhood of a university town should appoint at least one qualified research assistant who would have free access to their hospitals and have at the same time the facilities of the university laboratories, and that the head of these departments should act as advisor to the research worker. Laboratory assistance would be necessary, as the research worker should not be required to do a lot of mechanical work which could be quite efficiently done by a partially trained man. I would put the maximum annual cost for each research worker at £1500 to cover salary, assistance, and material. With the appointment of a number of such workers the problems of disease would thus be attacked along different aspects by a series of workers, all sufficiently remunerated to go on for several years, and advised by men of different ideas and different lines of thought. They would have facilities of the best, and I am confident that in a very short time the expenditure of money would be fully justified. My contention is that with available funds it is far better to endow the individual effort than to endow an institute which has certain disadvantages.

The history of medicine goes to show that the greatest discoveries and the greatest advances have been made by workers who have worked along independent lines, and who have not been under the control of special research and other committees, always on the outlook for reports and publications. Incidentally, I would add that I think it would be a good thing if the scientific medical journals could be suppressed for a few years, so that much of the undigested literature of to-day might find its way into the waste-paper basket before, and not after, publication.

Research in our universities has been badly organised, hampered on all sides by want of funds and by the lack of hospital facilities. If the money spent on the bricks and mortar, on the equipment, and on the maintenance had been spent on university laboratories already built and already fairly well equipped, then it would have been more abundant and probably more valuable. Everyone must recognise that in a University the heads of departments are busy with teaching and administration, and research must take a second place, but universities should be sufficiently financed to be able adequately to staff their department so as to relieve the man with the special capacity for research from much of the routine administrative and teaching work of the department. I would not free him altogether from teaching, because I think the divorce of teaching and research is extremely bad, particularly for the teacher, and in a lesser degree for the research worker. The University, however, should be able to relieve the research man from much routine work by giving him satisfactory assistants, and at the same time to encourage the spirit of research among its younger teachers.

An Appeal to Local Authorities.

It may be asked whether this is legitimate work for the local authorities. To me it appeals as essentially their work. Research deals not only with the discovery of the cause of the diseases, but with the means of protection against them; the funds for this must come mainly from the national purse and from local authorities. I am not dealing to-day with research under Government control, but would merely say in passing that it is not creditable to our country the way research, in all its branches, is starved. My appeal to-day is to the enlightened local authorities, that they should devote a certain amount of money to systematic research in the laboratories established in their neighbourhood just as they devote money to the treatment of disease. What a stimulus would be given to research if our local authorities were to give even *one-tenth of the money they are now spending on* administration to existing research laboratories.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED AUGUST 11TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 111 (last week, 126); scarlet fever, 1334; diphtheria, 787; enteric fever, 222; pneumonia, 499; puerperal fever, 58; puerperal pyrexia, 90; cerebro-spinal fever, 12; acute poliomyelitis, 10; acute polio-encephalitis, 1; encephalitis lethargica, 14; continued fever, 1; dysentery, 4; ophthalmia neonatorum, 128. No case of cholera, plague, or typhus fever was notified during the week.

The following counties each notified three or more cases of enteric fever:—London, 69; Bucks, 3; Devon, 5; Essex, 9; Hertford, 3; Kent, 6; Lancaster, 13; Middlesex, 9; Northumberland, 3; Nottingham, 9; Southampton, 3; Surrey, 45; Warwick, 7; Wilts, 4; Yorks, West Riding, 6. The total of 222 includes 147 cases of paratyphoid fever, of which 57 were notified in London and 35 in Surrey.

The number of patients in the Infectious Hospitals of the Metropolitan Asylums Board on August 14th–15th was as follows:—Small-pox, 11 under treatment; scarlet fever, 1614; diphtheria, 1618; enteric fever, 97; measles, 226; whooping-cough, 207; puerperal fever, 12 (plus 9 babies); encephalitis lethargica, 71; poliomyelitis, 12; "other diseases," 15. At St. Margaret's Hospital there were 18 babies with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 5 (1) from enteric fever, 11 (1) from measles, 6 (1) from scarlet fever, 22 (2) from whooping-cough, 22 (5) from diphtheria, 60 (19) from diarrhœa and enteritis under two years, and 15 (3) from influenza. The figures in parentheses are those for London itself.

The fatal cases of enteric fever outside London were reported from Liverpool, Salford, Preston, and Sheffield. Of the 20 fatal cases of whooping-cough outside London 3 were reported from Birmingham and 2 each from Liverpool, Manchester, and Newcastle-on-Tyne. Glasgow reported 7 in the same week. Belfast reported 5 fatal cases of measles. The youthful deaths from diarrhœa show scarcely any increase.

The number of stillbirths registered during the week was 254 in the great towns (corresponding to a rate of 42 per thousand births), including 45 in London.

THE LATE COLONEL J. ARNOTT.—The death occurred on August 18th at Kirtlebridge, Dumfriesshire, of Lieut.-Colonel James Arnott, formerly of the Indian Medical Service. The son of Dr. John Arnott, he was born in India in 1845, and went back to the East soon after qualifying in medicine in the University of Glasgow in 1866. He served throughout the Abyssinian Campaign of 1866–68, and was in Afghanistan in 1879 and the two following years, seeing service at Kandahar and being twice mentioned in despatches. He retired from the Indian Medical Service in 1898 after 31 years of medical work, during which he occupied the chairs of pathology and midwifery at the Grant Medical College, Bombay, and held appointments as honorary obstetric physician to the Sir J. Sejabhoy Hospital, and as physician in charge of the St. George's Hospital in the same city. After his retirement Colonel Arnott was a member of the board of the Simpson Memorial Hospital and the Victoria Hospital for Consumption at Edinburgh, and was for many years adviser to the Colonial Office for Scotland.

Medical News.

THE IRISH DENTISTS ACT.—The Dentists Act, which has received the signature of the Governor-General of the Irish Free State, imposes certain duties on the Medical Registration Council. In the first place, it will be the duty of the Council, on request by the Minister, to nominate three members of the Dental Board. These will be the first members of the Board to be appointed, and it will be their duty, together with the member nominated by the Executive Council, to proceed with the election of the remaining members. Further, after the establishment of the Register, the Medical Council will have the duty of satisfying itself that the standard of theoretical and practical knowledge required at the qualifying examinations in dentistry is such as to guarantee the possession of knowledge requisite for the efficient practice of dentistry or dental surgery. The Medical Council is, therefore, the supervising authority in regard to education, but all disciplinary powers are given to the Dental Board. In this respect the Irish Act differs from the law in force in Great Britain. In the form in which the Act passed, there is no interference with the privilege of registered medical practitioners to practise dentistry or dental surgery.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—On Monday, August 27th, a two weeks' course will begin at the Queen Mary's Hospital, Stratford. This is an all-day course, and instruction will be given in medicine, surgery, and the specialties. From Sept. 11th to Oct. 5th, on Tuesdays and Saturdays at 11 A.M., there will be lecture-demonstrations on Psychological Medicine at the Bethlem Royal Hospital. From Sept. 17th to 29th four courses have been arranged. The Queen's Hospital, Hackney-road, will give a course on Diseases of Children occupying the whole of each day. Lecture-demonstrations in ophthalmology will be given during the afternoon by the staff of the Royal Eye Hospital; an all-day course in orthopædics will be held at the Royal National Orthopædic Hospital; and the Westminster Hospital will give a course, also intensive, in medicine, surgery, and the specialties. From Sept. 26th to Oct. 17th a series of lecture-demonstrations in electrotherapy will be given at the Royal Free Hospital. Copies of all syllabuses and information about the General Course at the affiliated hospitals may be had from the Secretary of the Fellowship at 1, Wimpole-street, London, W. 1.

THE LATE MR. W. M. OAKDEN.—The death occurred on August 12th of William Marshall Oakden, B.Chir. Camb., F.R.C.S. Eng., medical superintendent of St. Luke's Hospital, Lowestoft. Mr. Oakden, who was in his forty-second year, was educated at Peterhouse, Cambridge, entering St. Thomas's Hospital with an entrance scholarship and taking the Bristowe medal. Qualifying in 1911 he served as house surgeon, casualty officer, and medical officer in the infectious wards of his own hospital. During the war he went out with the Salonika expeditionary force, and acted as temporary assistant surgeon at St. George's Hospital. After experience as senior assistant medical officer at Queen Mary's Hospital, Carshalton, he was put in charge of the large convalescent hospital at Lowestoft, where the Metropolitan Asylums Board deals with all its cases of adult surgical tuberculosis.

Vacancies.

For further information refer to the advertisement columns.

Albert Dock Hospital, Connaught-road, E.—Res. M.O. At rate of £110.

Barry Accident and Surgical Hospital.—H.S. At rate of £200.

Bath, Royal United Hospital.—H.P., H.S., and Asst. H.S. At rate of £120 and £100 respectively.

Bedford County Hospital.—H.S., also Asst. H.S. At rate of £175 and £130 respectively.

Bolingbroke Hospital, Wandsworth Common, S.W.—Res. M.O. £200.

Bradford, Children's Hospital.—H.S. £120.

Bristol General Hospital.—H.P.'s, H.S.'s, &c. All at rate of £100.

Bristol Royal Infirmary.—H.P.'s, H.S.'s. Also Dental H.S. Each at rate of £80.

Cairo, Egyptian Government Public Health Dept.—Director of Endemic Diseases Section. L.E. 900 to 1140.

Cairo, Egyptian University.—Faculty of Medicine: Professor of Forensic Medicine. L.E. 1500. Also Prof. of Clin. Surg., &c.

Calcutta School of Tropical Medicine and Hygiene.—Professor of Tropical Medicine.

Carlisle, Cumberland Infirmary.—H.S. At rate of £175. H.P. At rate of £155. Also H.S. to Special Depts. At rate of £150.

Carmarthen, Joint Counties Mental Hospital.—Jun. Asst. M.O. £300.

Chester Royal Infirmary.—H.P. £120.

Dreadnought Hospital, Greenwich.—H.P. and H.S. Each at rate of £110. Also Surgeon to Out-patients.

Hayward's Heath, King Edward VII. Memorial (Eliot) Hospital. Hon. Surg.

Hospital for Tropical Diseases, Endsleigh-gardens, W.C.—H.P. At rate of £110.

Hospital for Women, Soho-square, W.—Res. M.O. At rate of £100.

Hull, City and County of Kingston-upon-Hull.—Asst. M.O.H. £600.

Kingston-on-Thames, Surrey County Sanatorium, Milford, near Godalming.—Sen. Asst. Res. M.O. £500.

Leicester Royal Infirmary.—Res. M.O.'s. Each at rate of £125.

Lincoln County Hospital.—Jun. H.S. At rate of £150.

Liverpool, David Lewis Northern Hospital.—Surg. Reg. and Asst. Pathologist, Surg. Reg., Tutor and Asst. Pathologist. Each £145. Also Med. Reg. and Tutor. £120.

Lowestoft, St. Luke's Hospital.—Med. Supt. £800.

Manchester, Monsall Hospital for Infectious Diseases.—Second Asst. M.O. Also Jun. M.O. At rate of £375 and £350 respectively.

Manchester, Park Hospital, Davyhulme.—Three R.M.O.'s. One at rate of £150 and two at rate of £120.

Manchester, Royal Children's Hospital, Gartside-street.—Asst. M.O. At rate of £150.

Manchester, Royal Children's Hospital, Pendlebury.—Res. Surg. Officer. At rate of £125.

Metropolitan Ear, Nose and Throat Hospital, Fitzroy-square, W.—H.S. £150.

National Hospital for Diseases of the Heart, Westmoreland-street, W.—Res. M.O. At rate of £150.

Newcastle-upon-Tyne, Hospital for Sick Children.—Jun. H.S. At rate of £100. Also Res. Sen. H.S. and Res. P. Each at rate of £95.

Newport, Mon., Cefn Mably Hospital, Michaelstone-y-vedw.—Asst. Res. M.O. £200. Also Third Asst. Res. M.O. at South Wales Sanatorium, Talgarth, near Brecon. £200.

Nottingham City Mental Hospital.—Jun. Asst. M.O. £350.

Plymouth, South Devon and East Cornwall Hospital.—H.S. At rate of £50.

Prince of Wales's General Hospital, Tottenham, N.—Res. Anæsthetist. At rate of £120.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Asst. Res. M.O. At rate of £80.

Rochester, St. Bartholomew's Hospital. H.P. At rate of £175.

Royal Air Force Medical Service.—Commissions.

St. George's Hospital Medical School, S.W.—Pathologist and Lecturer in Pathology. £575.

St. Mary Abbot's Hospital, Kensington.—Part-time Pathologist, &c. £650.

St. Peter's Hospital for Stone, &c., Henrietta-street, Covent Garden, W.C.—H.S. At rate of £75.

Salford Municipal Maternity Home and Babies' Hospital, Seedley-terrace, Pendleton.—Asst. Maternity and Child Welfare M.O. £600.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—H.S. At rate of £100.

Truro, Royal Cornwall Infirmary.—H.S. £170.

University College Hospital Medical School.—Radcliffe Crocker Travelling Scholarship in Dermatology. £280.

University of London, S. Kensington, S.W.—William Julius Mickle Fellowship. £200.

Wandsworth Borough Council.—Locum Tenens, Asst. M.O.H., &c. £10 10s. weekly.

Weir Hospital, Grove-road, Balham, S.W.—Jun. Res. M.O. £150.

West London Hospital, Hammersmith-road, W.—H.P. and two H.S.'s. Each at rate of £100.

Western Australia Lunacy Dept.—Jun. Asst. Res. M.O. £456.

Weston-super-Mare Hospital.—Res. M.O. £130.

Wolverhampton and Staffordshire Hospital.—H.S. At rate of £150.

The Chief Inspector of Factories announces the following vacant appointments for Certifying Factory Surgeons:—Hawes (Yorks, North Riding), Youlgreave (Derbyshire), Southport (Lancashire), Torpoint (Cornwall), and Olney (Bucks).

Births, Marriages, and Deaths.

BIRTHS.

BYRD.—On August 19th, Dr. Elizabeth C. Byrd (née Powell), the wife of Dr. John D. Byrd, St. Aubyn, Cecil-avenue, Ashton-on-Mersey, of a son.

GODDARD.—On August 15th, at Lincoln House, Hemel Hempstead, to Gladys, wife of Dr. T. R. Goddard—a son.

RAINER.—On August 17th, at "Shirlands," Herne Hill, S.E. 24, to Kathleen, wife of Dr. Charles Farrell Rainer—a daughter.

MARRIAGES.

JARMAN—CUMMING.—On August 15th, at St. Marylebone Parish Church, W., Mr. Ronald Jarman, L.R.C.P. Lond., M.R.C.S. Eng., and Mary Putnam, only daughter of the late Mr. James W. Cumming, of Huddersfield, and Mrs. Cumming, of Haslemere, Surrey.

DEATHS.

SYME.—On August 14th, suddenly, William Smith Syme, Senr., M.D., F.R.F.P. & S. Glasg., F.R.S.E., of 11, Lynedoch-crescent, Glasgow.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Ingleby Lectures

ON

SOME RECENT ADVANCES IN OUR KNOWLEDGE OF RICKETS AND ALLIED DISEASES.

Delivered at the University of Birmingham

BY LEONARD G. PARSONS, M.D., F.R.C.P. LOND.,
PHYSICIAN TO THE CHILDREN'S AND GENERAL HOSPITALS, BIRMINGHAM.

LECTURE I.*

THE renaissance of medicine, or perhaps it were better to say the birth of physiology, occurred exactly 300 years ago, when the immortal William Harvey published his treatise "Exercitatio Anatomica de Motu Cordis et Sanguinis." It is interesting to speculate on the connexion between this event and the recognition of the disease which forms the subject upon which I have chosen to speak. There is no doubt that Harvey's discovery profoundly impressed the scientific world of his time; indeed, his work was universally accepted, and "inculcated as a canon in most of the medical schools in Europe" during his lifetime. I think that there can be no question that this discovery stimulated many of the doctors of his day to closer observation and led to the recognition of rickets. Although it seems certain that rickets existed at least 200 years before Harvey's day, yet it only appears for the first time in the list of diseases in the London yearly bills of mortality in the year 1634. During the early seventeenth century these bills seem only to have been printed in years of extraordinary mortality. The earliest known copies belong to the year 1625, and there are bills extant for 1629, 1630, 1631, 1632, 1633, 1634, &c., but it is only in the year 1634 that rickets occurs as one of the causes of death. It is probable, however, that Harvey's work had an even more important influence on the knowledge of rickets, since in the year "De Motu Cordis" was published, Francis Glisson was lecturer in Greek, and in the following year Dean of Gonville and Caius College, Harvey's own College. It surely must be something more than a mere coincidence that he should then turn his attention to medicine, proceeding to the degree of doctor of medicine in the year 1634. Glisson later became one of the members of a small society which met weekly in London for the purpose of promoting inquiries into natural and experimental philosophy, and which after the Reformation developed into the Royal Society. Seven members of this Society, all Fellows of the Royal College of Physicians, "communicated to each other observations concerning this new disease. From these it was thought proper to make extracts and compose an express treatise on the subject, the care of which was unanimously delegated to Drs. Glisson, Bates, and Regemorter. The plan at first agreed on was that each should take a separate part of the work and complete it. But on Dr. Glisson finishing his, which contained an investigation of the cause of the disease, to the satisfaction of the other two, but with many opinions peculiar to himself, they changed their design and committed to him the planning of the whole work that all its parts might be congruous and dependent on each other." This book, which it will be remembered bore the title "De Rachitide seu Morbo Puerili qui vulgo the Rickets dicitur," was a masterly treatise on what he considered to be an entirely new disease which had arisen some 30 years previously in Somersetshire and in his native county of Dorset. The impression created by this work was shown by the fact that rickets has ever since been known in Germany as the English disease.

Although Glisson attributed rickets to disturbed nutrition by arterial blood and believed that the bone changes were due to excessive vascularity, yet it is true to say that according to his conception rickets was a disease of the bony skeleton. He suggested the title rachitis for two reasons, partly because of its likeness to the word "rickets"—the name applied to the disease by the common people—and the other because the vertebral column was so frequently affected in this disease, ῥάχις being the Greek word for spine. Rickets, on the other hand, is probably derived from the Anglo-Saxon word wrickken (to twist), and was applied to the disease because of the deformities which characterised severe cases. This word has passed into common usage in our language; thus we speak of a rickety chair or table, a phrase which calls up in our minds the picture of a piece of furniture which can well be compared with that of a child suffering from severe rickets whose twisted limbs are ill-adapted to support its weight. Although it is true that the characteristic changes are to be found in the skeletal system, and particularly in that part of the skeleton which is growing rapidly, the view that rickets is a disease of bone is quite wrong. This idea, however, dominated the study of rickets for over 250 years, and it is only fitting that, as the birth of our knowledge of rickets can be claimed for an Englishman, its renaissance and the origin of the present conception of rickets should be shared equally by a Scotsman, Leonard Findlay, and an Englishman, Gowland Hopkins. The modern view of rickets, evolved during the last 15 to 20 years, is that the disease is a general nutritional or metabolic disorder which affects every system of the body, the early symptoms bearing no direct reference to the skeleton. Thus, rickets may show itself as a respiratory disorder in recurring attacks of bronchitis; as a gastro-intestinal affection in recurring diarrhœa; as a nervous disorder in tetany, convulsions, &c.; as a muscular disease in severe hypotonia; but eventually characteristic bone changes always occur. The development and proof of this theory has been in a large degree the work of numerous British and American investigators, and furnishes a most striking example of the interdependence of laboratory research and clinical medicine.

In order to understand how recent researches have added to our knowledge of the very complex problems of the ætiology and cure of rickets, it is necessary to have some knowledge of the radiographic appearances, the chemical processes involved in the deposition of bone, and the histological characters of normal and rachitic bone.

HISTOLOGY.

A longitudinal section of a long bone of an infant shows a clean cut end (epiphyseal line) to the shaft (diaphysis), and a disc of whitish cartilage (epiphyseal cartilage) between this and the bony epiphysis in those instances in which ossification of the epiphysis has occurred. In a rachitic bone quite a different picture is obtained. The width of the epiphyseal disc of cartilage is considerably increased. There is no epiphyseal line, but its place is taken by an irregular frayed end to the diaphysis. This frayed end, which is more vascular than normal, is usually scooped out and expanded laterally, the result of pressure, thus producing the clinical sign of enlargement of the epiphysis. To this altered extremity of the diaphysis the term metaphysis is applied.

Microscopical examination of the growing end of a normal bone reveals in passing from the epiphyseal cartilage to the diaphysis, first, ordinary hyaline cartilage followed by the zone of cartilage proliferation in which the cartilage cells become increased in number and then arranged in columns of 6 to 15 cells. The cells eventually become larger, and the number in each space increased. The cell columns are separated from each other by columns of hyaline matrix. This area is followed by the zone of provisional calcification in which lime salts are

deposited in the columns of matrix. As a result the columns become rigid and thus direct the budding capillaries from the marrow up against the cartilage cells, which are either destroyed by erosion or become lost in the medullary spaces. The columns themselves are then partly destroyed and partly act as centres round which osteoblasts arrange themselves and form bone which at first contains no calcium and is known as osteoid. In health this osteoid layer is only a narrow area in which calcium is soon deposited and true bone formed.

---

* Lecture II. will appear in a coming issue of THE LANCET.

In rickets this orderly arrangement is completely lost. The zone of cartilage proliferation is increased vertically and laterally, the columnar arrangement being at first manifest, but the cells in the column are more numerous and soon this design is lost and the cells appear as masses in a hyaline matrix. The zone of provisional calcification is absent, with the result that the marrow vessels grow in all directions. The osteoid layer is greatly thickened and forms the rachitic metaphysis; in it are islands of cartilage cells, wide spaces containing marrow, and in its deeper parts irregular depositions of calcium forming true bone and producing the characteristic dentate frayed appearance of the end of the metaphysis.

When healing takes place, the first thing to occur is the deposit of calcium in the cartilage where the zone of provisional calcification should have been. This at first is a thin irregular line, but as healing advances it thickens, depositions of calcium occur in the osteoid tissue, and the cartilage in the metaphysis gradually disappears. Osteoid tissue is also present under the periosteum in larger amounts than normally, producing irregular masses, buttressing, and the elimination of the sharp angles, borders and prominences of the long bones, and giving rise in the membrane bones of the skull to bossing.

The typical microscopical findings in rickets are: (1) the presence of large amounts of osteoid tissue; and (2) the substitution of disorder for order.

RADIOGRAPHIC MANIFESTATIONS.

These are best studied in the lower end of the radius. Except in very slight cases the bone trabeculæ are more coarse and blurred than normal. This coarsening increases as the disease advances and becomes very marked in severe cases. The appearance of the metaphysis varies with the degree of activity of the child, and, therefore, with the severity of the disease. In those children who are not too ill to be fairly active the end of the diaphysis is scooped out and expanded laterally, the so-called "champagne-glass" appearance. The distance between the epiphysis and the diaphysis is increased, and in place of the sharp epiphyseal line there is an irregular frayed margin. The frayed-out ends of bone gradually fade away towards the epiphyseal disc of cartilage until no bone shadow is seen. This is the characteristic appearance of the rachitic metaphysis in what has been called by Wimberger the active form of florid rickets. The appearance, however, is not seen in all the long bones even in this active form; for instance, it is never seen at the lower end of the humerus. If the disease is so severe that the child is unable to crawl or walk, the passive type of florid rickets is found. In this variety the distance between the epiphysis and diaphysis is still greater, but the transition from bone to cartilage is much more abrupt than in the active form of florid rickets. Although the end of the diaphysis is not sharply defined, yet the irregular fraying is not marked, neither is there any scooping out, nor lateral expansion of the diaphysis.

When healing commences a line of shadow appears at a short distance from the end of the metaphysis. This line is due to the formation of a zone of provisional calcification, and represents the epiphyseal line in a normal bone; its distance from the diaphysis depends upon the width of the rachitic zone of the osteoid tissue, and varies directly with the duration of the disease. As improvement continues the space between this line and the diaphysis is gradually filled in by bone in the form of striæ; the shadow of the whole bone increases in intensity; and the epiphyseal line become more dense and regular, until eventually the end of the bone shows a normal appearance. The epiphyseal line may remain slightly wavy for some time and the thickened striæ in the diaphysis behind the metaphysis can be distinguished for many months after healing is complete. In some cases of the passive type the first sign of healing is shown by the development of shadows at the margins of the metaphysis, suggesting the development of a mild degree of the cupping which is so characteristic of the active type. As the bone heals the subperiosteal osteoid tissue also ossifies and becomes evident in the radiogram along the shafts of the long bones, particularly the radius, ulna, fibula, and humerus.

MECHANISM OF THE DEPOSITION OF CALCIUM PHOSPHATE AS BONE.

This is a somewhat complicated problem, but viewed in its simplest terms we may, with Howland, regard the serum and circulatory fluids as normally saturated or supersaturated solutions, in which the calcium phosphate of bone is in equilibrium with the dissolved salt and this in turn with calcium and phosphate ions. This relationship can be expressed thus:—

$$[Ca^{++}]^3 + [PO_4^{\equiv}]^2 \rightleftharpoons Ca_3(PO_4)_2 \rightleftharpoons Ca_3(PO_4)_2$$

Ionised. In solution unionised. Solid in bone.

An increase in calcium or phosphate ions will cause the reaction to proceed to the right and result in the deposit of bone, whereas a decrease in concentration would result in some of the solid calcium phosphate in bone going into solution, the reaction proceeding to the left. According to mass action law, at equilibrium the product of the concentration on one side of the equation divided by the product of concentration on the other side is constant at constant temperatures, and therefore:—

$$[Ca^{++}]^3 \times [PO_4^{\equiv}]^2 = K[Ca_3(PO_4)_2]$$

Now *tertiary* calcium phosphate is a sparingly soluble salt and in such—

$$[Ca^{++}]^3 \times [PO_4^{\equiv}]^2 = K.$$

This *K* is called the solubility product constant and whenever the product of the concentration of calcium and phosphate ions becomes greater than the solubility product, solid calcium phosphate will be deposited.

The problem is, however, not quite so simple as this, and at least one other factor must be taken into account—i.e., the presence in the serum of carbon dioxide in considerable concentrations. This has an influence on tertiary calcium phosphate which may be expressed thus:—

$$Ca_3(PO_4)_2 + 2\,H_2CO_3 \rightleftharpoons 2\,CaHPO_4 + Ca(HCO_3)_2 \rightleftharpoons [Ca^{++}]^2 + [HPO_4^{=}]^2 + [Ca^{++}] + [HCO_3^{-}]^2$$

If the carbon dioxide tension of this solution be reduced, the reaction will proceed to the left and calcium phosphate will be deposited if the solubility product is exceeded, as it will be, since the solution is saturated. Now when the plasma substances, dicalcium phosphate and calcium bicarbonate, arrive at the osteoid and diffuse into the interstitial spaces, the concentration of carbonic acid falls below the plasma level and therefore precipitation occurs.

In rickets the bicarbonate factor is unaltered from the normal, but calcium and/or phosphorus may be. An index of the reduction in the plasma of the material required for calcification could be obtained if it were possible directly to measure calcium and phosphorus ions. Unfortunately, there is no generally accepted method of doing this, but Howland

development [illegible] of ossification. The beginning of ossification in the embryo is one of the stumbling-blocks in Howland's theory, for whilst a saturated solution might deposit calcium phosphate on coming into contact with solid bone, in embryonic cartilage there is no such bone. Howland's theory is the more commonly accepted, and his rule is in the main borne out by clinical observations; but it breaks down in renal rickets, and in my opinion the calcium phosphorus ratio is of even greater importance than the calcium phosphorus product.

Both Howland and Robison hold that rachitic bone is just as able to deposit bone as is the normal bone—i.e., the fault does not lie in the bone but in the fluids that bathe it. Robison states that the phosphatase can be demonstrated both in rachitic and normal bone, and Howland bases his argument on some experiments carried out by Shipley, Kramer, and himself, some of which it was my privilege to see. Slices of rachitic bone were placed in blood serum obtained from a normal child, or in aqueous solutions containing calcium and inorganic phosphate in which the concentrations of phosphorus and calcium approximated to those of normal blood serum. These were then incubated at 37° C. and after a time typical calcification occurred. Such calcification, however, did not occur when the slices were placed in serum from a rachitic child or in aqueous solutions if the concentration of calcium and phosphorus were inadequate. Hence rachitic bone tissue is just as able to deposit calcium phosphate as is normal bone tissue, and it remains uncalcified only so long as calcium and phosphorus are supplied to it in such low ionic concentrations that precipitation of tertiary calcium phosphate cannot take place. Rickets, therefore, is not a bone disease, and the deformities are due to stresses and strains upon a soft bone and are really mechanical and not pathological changes.

In the normal infant or young child 100 c.cm. of blood serum contains 10–11 mg. of calcium and 5–6 mg. of inorganic phosphorus, whereas in rickets there is considerable diminution in phosphorus, which may even be as low as 1 mg. per cent. A low serum calcium is rarely found with uncomplicated rickets, but does occur in tetany, in cœliac, and, sometimes, in renal rickets. In rats, on the other hand, it is possible to produce rickets associated with either low calcium and normal phosphorus (low calcium rickets), or normal calcium and low phosphorus values (low phosphorus rickets) by feeding respectively with a diet that is defective in calcium or in phosphorus. A low concentration of either of these two elements in the serum can thus occur if the dietary is insufficient, but may also occur even when the dietetic supply is normal if absorption from the bowel is impaired. If my view is correct, that the ratio of calcium to phosphorus is more important than the actual concentration, it is possible for rickets to occur even if the absorption of both elements is normal, if there is some impairment of excretion. Calcium is chiefly excreted into the large intestine and also to a small degree in the urine. There does not appear to be any primary defect in urinary or intestinal calcium excretion which ensures abnormal calcium retention; indeed, hypercalcæmia induced experimentally soon leads to death. Phosphorus, on the other hand, is excreted chiefly by the kidneys, and here we have a very different state of affairs, since in chronic intestinal nephritis there is phosphorus retention, the calcium phosphorus ratio is altered, and we have a condition which should produce a low calcium rickets, and this in fact occurs (renal rickets).

The modern conception, as I understand it, is, therefore, that rickets is a disorder of calcium and phosphate metabolism resulting from defective absorption (and retention) of these elements from the intestine and rarely from defective excretion of phosphate. As a corollary we can say that rickets can be prevented or cured by taking measures to ensure the normal absorption of calcium and phosphorus from the bowel, and their normal retention in the body.

The questions which recent research has endeavoured to answer are: 1. What are the factors influencing calcium and phosphorus absorption from the bowel? 2. What are the ætiological factors concerned in the production of rickets and how can rickets be cured? These two questions are really interdependent, or are even two ways of asking the same question, but it will be convenient to consider them both and to consider the second before the first.

ÆTIOLOGICAL FACTORS.

Rickets has no single specific constant ætiological factor, but may arise from defective hygienic surroundings, particularly lack of sunshine, or from dietetic causes. There have thus developed two schools of thought—by the one rickets is regarded as a primary dietetic disease, and by the other as due to defective hygiene. The controversy between the protagonists of these theories has been severe, at times even acrimonious, although the results of recent investigation have tended considerably to the restoration of harmonious relations.

The importance of defective hygiene has been emphasised by the Glasgow School as the result of an extensive series of investigations. The hygienic conditions of children suffering from rickets were contrasted with those of normal children in the same social scale and it was shown that the rachitic children were obviously defective in fresh air and exercise, diet being apparently of secondary importance. Two of the Glasgow workers, Hutchison and Shah, investigated the occurrence of rickets in India, and found that, while low caste children did not develop rickets, the disease was common amongst high caste children who lived under the "purdah" system. Late rickets was also common amongst "purdah" women in spite of the fact that their diet and that of their children contained far more fat than did that of the low caste women.

The fact that rickets is a disease of temperate zones and very rarely occurs at high altitudes or in tropical countries, except under the conditions just described, has been known for years. But that this immunity was due to sunlight, and that sunlight could prevent and cure rickets, has only been generally recognised recently, although as long ago as 1890 Palm drew attention to the importance of sunlight in this connexion. The value of sunlight was, however, not appreciated until Huldschinsky, in 1919, showed that rickets could be cured by the action of ultra-violet rays, and Hess and Unger, in 1921, conclusively demonstrated the cure of rickets by sunlight. Although Findlay regarded lack of exercise as being the essential factor of defective hygiene, the balance of evidence points very strongly to the conclusion that the results of defective hygiene are in reality due to lack of sunshine.

Since the original statement of Kassovitz in 1884 many observers have commented upon the seasonal

deposited in the columns of matrix. As a result the columns become rigid and thus direct the budding capillaries from the marrow up against the cartilage cells, which are either destroyed by erosion or become lost in the medullary spaces. The columns themselves are then partly destroyed and partly act as centres round which osteoblasts arrange themselves and form bone which at first contains no calcium and is known as osteoid. In health this osteoid layer is only a narrow area in which calcium is soon deposited and true bone formed.

In rickets this orderly arrangement is completely lost. The zone of cartilage proliferation is increased vertically and laterally, the columnar arrangement being at first manifest, but the cells in the column are more numerous and soon this design is lost and the cells appear as masses in a hyaline matrix. The zone of provisional calcification is absent, with the result that the marrow vessels grow in all directions. The osteoid layer is greatly thickened and forms the rachitic metaphysis; in it are islands of cartilage cells, wide spaces containing marrow, and in its deeper parts irregular depositions of calcium forming true bone and producing the characteristic dentate frayed appearance of the end of the metaphysis.

When healing takes place, the first thing to occur is the deposit of calcium in the cartilage where the zone of provisional calcification should have been. This at first is a thin irregular line, but as healing advances it thickens, depositions of calcium occur in the osteoid tissue, and the cartilage in the metaphysis gradually disappears. Osteoid tissue is also present under the periosteum in larger amounts than normally, producing irregular masses, buttressing, and the elimination of the sharp angles, borders and prominences of the long bones, and giving rise in the membrane bones of the skull to bossing.

The typical microscopical findings in rickets are: (1) the presence of large amounts of osteoid tissue; and (2) the substitution of disorder for order.

RADIOGRAPHIC MANIFESTATIONS.

These are best studied in the lower end of the radius. Except in very slight cases the bone trabeculæ are more coarse and blurred than normal. This coarsening increases as the disease advances and becomes very marked in severe cases. The appearance of the metaphysis varies with the degree of activity of the child, and, therefore, with the severity of the disease. In those children who are not too ill to be fairly active the end of the diaphysis is scooped out and expanded laterally, the so-called "champagne-glass" appearance. The distance between the epiphysis and the diaphysis is increased, and in place of the sharp epiphyseal line there is an irregular frayed margin. The frayed-out ends of bone gradually fade away towards the epiphyseal disc of cartilage until no bone shadow is seen. This is the characteristic appearance of the rachitic metaphysis in what has been called by Wimberger the active form of florid rickets. The appearance, however, is not seen in all the long bones even in this active form; for instance, it is never seen at the lower end of the humerus. If the disease is so severe that the child is unable to crawl or walk, the passive type of florid rickets is found. In this variety the distance between the epiphysis and diaphysis is still greater, but the transition from bone to cartilage is much more abrupt than in the active form of florid rickets. Although the end of the diaphysis is not sharply defined, yet the irregular fraying is not marked, neither is there any scooping out, nor lateral expansion of the diaphysis.

When healing commences a line of shadow appears at a short distance from the end of the metaphysis. This line is due to the formation of a zone of provisional calcification, and represents the epiphyseal line in a normal bone; its distance from the diaphysis depends upon the width of the rachitic zone of the osteoid tissue, and varies directly with the duration of the disease. As improvement continues the space between this line and the diaphysis is gradually filled in by bone in the form of striæ; the shadow of the whole bone increases in intensity; and the epiphyseal line become more dense and regular, until eventually the end of the bone shows a normal appearance. The epiphyseal line may remain slightly wavy for some time and the thickened striæ in the diaphysis behind the metaphysis can be distinguished for many months after healing is complete. In some cases of the passive type the first sign of healing is shown by the development of shadows at the margins of the metaphysis, suggesting the development of a mild degree of the cupping which is so characteristic of the active type. As the bone heals the subperiosteal osteoid tissue also ossifies and becomes evident in the radiogram along the shafts of the long bones, particularly the radius, ulna, fibula, and humerus.

MECHANISM OF THE DEPOSITION OF CALCIUM PHOSPHATE AS BONE.

This is a somewhat complicated problem, but viewed in its simplest terms we may, with Howland, regard the serum and circulatory fluids as normally saturated or supersaturated solutions, in which the calcium phosphate of bone is in equilibrium with the dissolved salt and this in turn with calcium and phosphate ions. This relationship can be expressed thus:—

$$[\mathrm{Ca}^{++}]^3 + [\mathrm{PO}_4^{\equiv}]^2 \rightleftharpoons \mathrm{Ca}_3(\mathrm{PO}_4)_2 \rightleftharpoons \mathrm{Ca}_3(\mathrm{PO}_4)_2$$

Ionised. In solution unionised. Solid in bone.

An increase in calcium or phosphate ions will cause the reaction to proceed to the right and result in the deposit of bone, whereas a decrease in concentration would result in some of the solid calcium phosphate in bone going into solution, the reaction proceeding to the left. According to mass action law, at equilibrium the product of the concentration on one side of the equation divided by the product of concentration on the other side is constant at constant temperatures, and therefore:—

$$[\mathrm{Ca}^{++}]^3 \times [\mathrm{PO}_4^{\equiv}]^2 = K[\mathrm{Ca}_3(\mathrm{PO}_4)_2]$$

Now tertiary calcium phosphate is a sparingly soluble salt and in such—

$$[\mathrm{Ca}^{++}]^3 \times [\mathrm{PO}_4^{\equiv}]^2 = K.$$

This *K* is called the solubility product constant and whenever the product of the concentration of calcium and phosphate ions becomes greater than the solubility product, solid calcium phosphate will be deposited.

The problem is, however, not quite so simple as this, and at least one other factor must be taken into account—i.e., the presence in the serum of carbon dioxide in considerable concentrations. This has an influence on tertiary calcium phosphate which may be expressed thus:—

$$\mathrm{Ca}_3(\mathrm{PO}_4)_2 + 2\,\mathrm{H}_2\mathrm{CO}_3 \rightleftharpoons 2\,\mathrm{CaHPO}_4 + \mathrm{Ca}(\mathrm{HCO}_3)_2 \rightleftharpoons [\mathrm{Ca}^{++}]^2 + [\mathrm{HPO}_4^{=}]^2 + [\mathrm{Ca}^{++}] + [\mathrm{HCO}_3^{-}]^2$$

If the carbon dioxide tension of this solution be reduced, the reaction will proceed to the left and calcium phosphate will be deposited if the solubility product is exceeded, as it will be, since the solution is saturated. Now when the plasma substances, dicalcium phosphate and calcium bicarbonate, arrive at the osteoid and diffuse into the interstitial spaces, the concentration of carbonic acid falls below the plasma level and therefore precipitation occurs.

In rickets the bicarbonate factor is unaltered from the normal, but calcium and/or phosphorus may be. An index of the reduction in the plasma of the material required for calcification could be obtained if it were possible directly to measure calcium and phosphorus ions. Unfortunately, there is no generally accepted method of doing this, but Howland

development before the [illegible] of ossification. The beginning of ossification in the embryo is one of the stumbling-blocks in Howland's theory, for whilst a saturated solution might deposit calcium phosphate on coming into contact with solid bone, in embryonic cartilage there is no such bone. Howland's theory is the more commonly accepted, and his rule is in the main borne out by clinical observations; but it breaks down in renal rickets, and in my opinion the calcium phosphorus ratio is of even greater importance than the calcium phosphorus product.

Both Howland and Robison hold that rachitic bone is just as able to deposit bone as is the normal bone—i.e., the fault does not lie in the bone but in the fluids that bathe it. Robison states that the phosphatase can be demonstrated both in rachitic and normal bone, and Howland bases his argument on some experiments carried out by Shipley, Kramer, and himself, some of which it was my privilege to see. Slices of rachitic bone were placed in blood serum obtained from a normal child, or in aqueous solutions containing calcium and inorganic phosphate in which the concentrations of phosphorus and calcium approximated to those of normal blood serum. These were then incubated at 37° C. and after a time typical calcification occurred. Such calcification, however, did not occur when the slices were placed in serum from a rachitic child or in aqueous solutions if the concentration of calcium and phosphorus were inadequate. Hence rachitic bone tissue is just as able to deposit calcium phosphate as is normal bone tissue, and it remains uncalcified only so long as calcium and phosphorus are supplied to it in such low ionic concentrations that precipitation of tertiary calcium phosphate cannot take place. Rickets, therefore, is not a bone disease, and the deformities are due to stresses and strains upon a soft bone and are really mechanical and not pathological changes.

In the normal infant or young child 100 c.cm. of blood serum contains 10–11 mg. of calcium and 5–6 mg. of inorganic phosphorus, whereas in rickets there is considerable diminution in phosphorus, which may even be as low as 1 mg. per cent. A low serum calcium is rarely found with uncomplicated rickets, but does occur in tetany, in cœliac, and, sometimes, in renal rickets. In rats, on the other hand, it is possible to produce rickets associated with either low calcium and normal phosphorus (low calcium rickets), or normal calcium and low phosphorus values (low phosphorus rickets) by feeding respectively with a diet that is defective in calcium or in phosphorus. A low concentration of either of these two elements in the serum can thus occur if the dietary is insufficient, but may also occur even when the dietetic supply is normal if absorption from the bowel is impaired. If my view is correct, that the ratio of calcium to phosphorus is more important than the actual concentration, it is possible for rickets to occur even if the absorption of both elements is normal, if there is some impairment of excretion. Calcium is chiefly excreted into the large intestine and also to a small degree in the urine. There does not appear to be any primary defect in urinary or intestinal calcium excretion which ensures abnormal calcium retention; indeed, hypercalcæmia induced experimentally soon leads to death. Phosphorus, on the other hand, is excreted chiefly by the kidneys, and here we have a very different state of affairs, since in chronic intestinal nephritis there is phosphorus retention, the calcium phosphorus ratio is altered, and we have a condition which should produce a low calcium rickets, and this in fact occurs (renal rickets).

The modern conception, as I understand it, is, therefore, that rickets is a disorder of calcium and phosphate metabolism resulting from defective absorption (and retention) of these elements from the intestine and rarely from defective excretion of phosphate. As a corollary we can say that rickets can be prevented or cured by taking measures to ensure the normal absorption of calcium and phosphorus from the bowel, and their normal retention in the body.

The questions which recent research has endeavoured to answer are: 1. What are the factors influencing calcium and phosphorus absorption from the bowel? 2. What are the ætiological factors concerned in the production of rickets and how can rickets be cured? These two questions are really interdependent, or are even two ways of asking the same question, but it will be convenient to consider them both and to consider the second before the first.

ÆTIOLOGICAL FACTORS.

Rickets has no single specific constant ætiological factor, but may arise from defective hygienic surroundings, particularly lack of sunshine, or from dietetic causes. There have thus developed two schools of thought—by the one rickets is regarded as a primary dietetic disease, and by the other as due to defective hygiene. The controversy between the protagonists of these theories has been severe, at times even acrimonious, although the results of recent investigation have tended considerably to the restoration of harmonious relations.

The importance of defective hygiene has been emphasised by the Glasgow School as the result of an extensive series of investigations. The hygienic conditions of children suffering from rickets were contrasted with those of normal children in the same social scale and it was shown that the rachitic children were obviously defective in fresh air and exercise, diet being apparently of secondary importance. Two of the Glasgow workers, Hutchison and Shah, investigated the occurrence of rickets in India, and found that, while low caste children did not develop rickets, the disease was common amongst high caste children who lived under the "purdah" system. Late rickets was also common amongst "purdah" women in spite of the fact that their diet and that of their children contained far more fat than did that of the low caste women.

The fact that rickets is a disease of temperate zones and very rarely occurs at high altitudes or in tropical countries, except under the conditions just described, has been known for years. But that this immunity was due to sunlight, and that sunlight could prevent and cure rickets, has only been generally recognised recently, although as long ago as 1890 Palm drew attention to the importance of sunlight in this connexion. The value of sunlight was, however, not appreciated until Huldschinsky, in 1919, showed that rickets could be cured by the action of ultra-violet rays, and Hess and Unger, in 1921, conclusively demonstrated the cure of rickets by sunlight. Although Findlay regarded lack of exercise as being the essential factor of defective hygiene, the balance of evidence points very strongly to the conclusion that the results of defective hygiene are in reality due to lack of sunshine.

Since the original statement of Kassovitz in 1884 many observers have commented upon the seasonal

deposited in the columns of matrix. As a result the columns become rigid and thus direct the budding capillaries from the marrow up against the cartilage cells, which are either destroyed by erosion or become lost in the medullary spaces. The columns themselves are then partly destroyed and partly act as centres round which osteoblasts arrange themselves and form bone which at first contains no calcium and is known as osteoid. In health this osteoid layer is only a narrow area in which calcium is soon deposited and true bone formed.

In rickets this orderly arrangement is completely lost. The zone of cartilage proliferation is increased vertically and laterally, the columnar arrangement being at first manifest, but the cells in the column are more numerous and soon this design is lost and the cells appear as masses in a hyaline matrix. The zone of provisional calcification is absent, with the result that the marrow vessels grow in all directions. The osteoid layer is greatly thickened and forms the rachitic metaphysis; in it are islands of cartilage cells, wide spaces containing marrow, and in its deeper parts irregular depositions of calcium forming true bone and producing the characteristic dentate frayed appearance of the end of the metaphysis.

When healing takes place, the first thing to occur is the deposit of calcium in the cartilage where the zone of provisional calcification should have been. This at first is a thin irregular line, but as healing advances it thickens, depositions of calcium occur in the osteoid tissue, and the cartilage in the metaphysis gradually disappears. Osteoid tissue is also present under the periosteum in larger amounts than normally, producing irregular masses, buttressing, and the elimination of the sharp angles, borders and prominences of the long bones, and giving rise in the membrane bones of the skull to bossing.

The typical microscopical findings in rickets are: (1) the presence of large amounts of osteoid tissue; and (2) the substitution of disorder for order.

RADIOGRAPHIC MANIFESTATIONS.

These are best studied in the lower end of the radius. Except in very slight cases the bone trabeculæ are more coarse and blurred than normal. This coarsening increases as the disease advances and becomes very marked in severe cases. The appearance of the metaphysis varies with the degree of activity of the child, and, therefore, with the severity of the disease. In those children who are not too ill to be fairly active the end of the diaphysis is scooped out and expanded laterally, the so-called "champagne-glass" appearance. The distance between the epiphysis and the diaphysis is increased, and in place of the sharp epiphyseal line there is an irregular frayed margin. The frayed-out ends of bone gradually fade away towards the epiphyseal disc of cartilage until no bone shadow is seen. This is the characteristic appearance of the rachitic metaphysis in what has been called by Wimberger the active form of florid rickets. The appearance, however, is not seen in all the long bones even in this active form; for instance, it is never seen at the lower end of the humerus. If the disease is so severe that the child is unable to crawl or walk, the passive type of florid rickets is found. In this variety the distance between the epiphysis and diaphysis is still greater, but the transition from bone to cartilage is much more abrupt than in the active form of florid rickets. Although the end of the diaphysis is not sharply defined, yet the irregular fraying is not marked, neither is there any scooping out, nor lateral expansion of the diaphysis.

When healing commences a line of shadow appears at a short distance from the end of the metaphysis. This line is due to the formation of a zone of provisional calcification, and represents the epiphyseal line in a normal bone; its distance from the diaphysis depends upon the width of the rachitic zone of osteoid tissue, and varies directly with the duration of the disease. As improvement continues the space between this line and the diaphysis is gradually filled in by bone in the form of striæ; the shadow of the whole bone increases in intensity; and the epiphyseal line become more dense and regular, until eventually the end of the bone shows a normal appearance. The epiphyseal line may remain slightly wavy for some time and the thickened striæ in the diaphysis behind the metaphysis can be distinguished for many months after healing is complete. In some cases of the passive type the first sign of healing is shown by the development of shadows at the margins of the metaphysis, suggesting the development of a mild degree of the cupping which is so characteristic of the active type. As the bone heals the subperiosteal osteoid tissue also ossifies and becomes evident in the radiogram along the shafts of the long bones, particularly the radius, ulna, fibula, and humerus.

MECHANISM OF THE DEPOSITION OF CALCIUM PHOSPHATE AS BONE.

This is a somewhat complicated problem, but viewed in its simplest terms we may, with Howland, regard the serum and circulatory fluids as normally saturated or supersaturated solutions, in which the calcium phosphate of bone is in equilibrium with the dissolved salt and this in turn with calcium and phosphate ions. This relationship can be expressed thus:—

$$\underset{\text{Ionised.}}{[Ca^{++}]^3 + [PO_4^{\equiv}]^2} \rightleftharpoons \underset{\text{In solution unionised.}}{Ca_3(PO_4)_2} \rightleftarrows \underset{\text{Solid in bone.}}{Ca_3(PO_4)_2}$$

An increase in calcium or phosphate ions will cause the reaction to proceed to the right and result in the deposit of bone, whereas a decrease in concentration would result in some of the solid calcium phosphate in bone going into solution, the reaction proceeding to the left. According to mass action law, at equilibrium the product of the concentration on one side of the equation divided by the product of concentration on the other side is constant at constant temperatures, and therefore:—

$$[Ca^{++}]^3 \times [PO_4^{\equiv}]^2 = K[Ca_3(PO_4)_2]$$

Now tertiary calcium phosphate is a sparingly soluble salt and in such—

$$[Ca^{++}]^3 \times [PO_4^{\equiv}]^2 = K.$$

This K is called the solubility product constant and whenever the product of the concentration of calcium and phosphate ions becomes greater than the solubility product, solid calcium phosphate will be deposited.

The problem is, however, not quite so simple as this, and at least one other factor must be taken into account—i.e., the presence in the serum of carbon dioxide in considerable concentrations. This has an influence on tertiary calcium phosphate which may be expressed thus:—

$$Ca_3(PO_4)_2 + 2\,H_2CO_3 \rightleftarrows 2\,CaHPO_4 + Ca(HCO_3)_2 \rightleftarrows [Ca^{++}]^2 + [HPO_4^{=}]^2 + [Ca^{++}] + [HCO_3^{-}]^2$$

If the carbon dioxide tension of this solution be reduced, the reaction will proceed to the left and calcium phosphate will be deposited if the solubility product is exceeded, as it will be, since the solution is saturated. Now when the plasma substances, dicalcium phosphate and calcium bicarbonate, arrive at the osteoid and diffuse into the interstitial spaces, the concentration of carbonic acid falls below the plasma level and therefore precipitation occurs.

In rickets the bicarbonate factor is unaltered from the normal, but calcium and/or phosphorus may be. An index of the reduction in the plasma of the material required for calcification could be obtained if it were possible directly to measure calcium and phosphorus ions. Unfortunately, there is no generally accepted method of doing this, but Howland

milk. Skim milk, however, was easily procurable and was largely used for the feeding of infants. As a result many of these children developed nutritional disorders (dystrophia alipogenetica) often associated with xerophthalmia, which, in many instances, passed on to total blindness. The proof that this condition was due to lack of fat was forthcoming when the Danish Government took over the supplies of butter, rationed it, and allowed 250 g. weekly to each individual, with the result that xerophthalmia immediately ceased. Bloch, who described these cases, emphasised the fact that in spite of the absence of fat these children rarely developed rickets, and he concluded that absence of vitamin A caused xerophthalmia but did not produce rickets. By feeding rats on a diet deficient, amongst other things, in fat, rickets and xerophthalmia can be produced experimentally.

In 1920 Gowland Hopkins showed that it was possible to destroy vitamin A in butter and cod-liver oil by heat and aeration, and in 1922 McCollum and his co-workers found that cod-liver oil so treated would no longer cure experimental xerophthalmia but would cure rickets. It appears clear, then, that closely associated with vitamin A is another fat-soluble vitamin which has antirachitic properties, and this is called vitamin D. Cod-liver oil is a good source of both vitamins, but cow's milk, whilst rich in vitamin A, is a poor source of vitamin D. The fact that some fats contain considerable amounts of vitamin A and but little vitamin D is the probable explanation of the failure of some workers to confirm Mellanby's experiments.

It is probable that the curative action of sunlight and artificial ultra-violet irradiation in rickets is due to the synthesis of vitamin D by the activation of ergosterol, or some similar sterol, found in association with cholesterol in the skin. Indeed, irradiated ergosterol is so potent that it has been suggested that it is pure vitamin D. Evidence that irradiation does produce vitamin D *in situ* is found in the fact that rats fed on a dietary producing the low phosphorus type of rickets develop an alkalinity of the fæces, the pH of which can be reduced, even to the acid side of neutrality, by irradiation or by the administration of irradiated ergosterol or cod-liver oil. Further evidence that irradiation of the cholesterol (or ergosterol) of the skin has a curative action is found in the observation of Hume, Henderson-Smith, and Lucas that inunction of irradiated cholesterol into the skin of rabbits and rats fed on a rickets-producing dietary prevented the development of rickets.

Whence comes the vitamin D present in cod-liver oil? It has been stated that this is obtained from the green algæ and diatoms (plankton) in the upper waters of the ocean, and that in these vitamin D is synthesised under the influence of sunlight. This plankton constitutes the food of small fish, which in their turn form the diet of the cod, and in the latter the vitamin is largely housed in the liver. The most recent researches, however, show that, whilst the marine diatom is a rich source of vitamin A, it contains no vitamin D, and the suggestion has been made that, both in relation to green plankton and green vegetables, which contain much vitamin A but little or any D, the same mistake has been made as in the earlier work of Mellanby on fats when no differentiation was made between the A and D vitamins. Moreover, Bills has shown that the principal food of the Newfoundland cod is the caplin, but that this does not contain enough vitamin D to account for the amount of vitamin which is accumulated by the cod during its midsummer period of fattening, and he therefore suggests that the vitamin may be synthesised by the cod.

The exposure of an animal to sunlight raises the content of vitamin D in its milk, and for this reason cow's milk shows a seasonal variation in vitamin D content which is related to similar seasonal variations in the incidence of rickets. The content of vitamin D, however, is not greatly increased by sunlight, but can, on the other hand, be considerably augmented by exposing the animal to ultra-violet rays from artificial sources, although such milk will not compare in antirachitic power with milk irradiated directly. It seems evident, therefore, that during the winter months breast milk must be considerably poorer in vitamin D than in the summer. However, it has been proved, as in the case of cow's milk, that the antirachitic properties of human milk can be increased by the irradiation of the mother, and that if cod-liver oil be given to her, the vitamin D can pass into her milk. Although it is a matter of universal clinical observation that rickets is far less common in children who are breast-fed, the question of the antirachitic effect of human milk and its relationship to vitamin D is one of great interest and difficulty. This difficulty will become even greater if confirmation is obtained of some recent experiments of Hess, from which he concludes that human milk is exceedingly poor in the antirachitic substance, and that its high protective power in rickets cannot be ascribed to that factor. McCollum states that animal experiments make it clear that faulty nutrition of the mother during pregnancy and the early part of the nursing period may so debilitate her young that later a diet which should protect against rickets may fail to do so, and, according to Greenbaum, if the maternal diet during the last three months of pregnancy is made approximately correct in caloric and mineral intake, rickets will not be absolutely prevented, but the mother's diet will have a controlling influence in the development of the disease in the offspring.

Rickets, however, does frequently occur in breast-fed premature children, twins, and particularly in dark-skinned Italian and negro children living in North American cities. Prolongation of breast-feeding into the second year of life is also very liable to produce rickets. The conditions under which Eskimo children live are of great interest in this connexion. In Greenland rickets does not exist, despite the fact that children are nursed until the age of 2 to 4 years, whereas in Labrador, although the children are much more exposed to sunshine, rickets is almost universal. The Greenland Eskimo, contrary to popular belief, eats little fat, but partakes freely of uncooked fish, birds, seals, &c., and the freedom from rickets is probably due to the presence in this diet of considerable quantities of vitamin D derived from the fish on which the birds and seals feed. The Labrador Eskimo, on the other hand, cooks his food, a large proportion of which is prepared or tinned, and eats very little vegetables (Thomas).

Calcium and Phosphorus.

From what has previously been stated, it is obvious that another important factor in the dietary is an ample supply of calcium and phosphorus. Adequate supplies of vitamin D or sunshine will prevent or cure rickets even when a baby is taking a diet which, from deficiency in calcium, phosphorus, or vitamin, would otherwise produce rickets.

Of all the factors concerned in the prevention of rickets, exposure of the body to sunshine and the preservation of the natural habitat of the child and diet of the mother are probably the most important. As clothing increased, and with it the urbanisation of society, the migration into cities and darkened dwellings, or, as in the case of the negro peoples, if movement occurred into more temperate zones, or, as in the case of the Labrador Eskimo, the maternal diet so changed that the supply of vitamin D diminished, rickets developed even in breast-fed children, but with more certainty in those artificially fed. Thus we have the appearance and development of rickets associated with the progress of civilisation, and in particular, with the rise of industrialism and the decline of breast-feeding.

As a result of these recent advances in our knowledge of the ætiology of rickets, the question may well be asked: was Glisson right in his view that rickets was a disease which had made its appearance for the first time but a few years before his monograph was written? It is true that the factors necessary for the production of rickets have been present, at incidence of rickets. The greatest incidence of the disease is in the late winter and early spring months—e.g., January to May—but the seasonal variations are much more marked in countries with a considerable amount of sunshine, such as Canada, the United States of America, and Austria, than in countries like the British Isles in which, indeed, the season variations are not very obvious. It is interesting to note that coincident with the seasonal incidence of rickets there is a seasonal decrease in the calcium and phosphorus of the blood. Recent observations by Brown and Tisdall, in Toronto, have shown that there is a sharp rise in the antirachitic effect of sunshine about the beginning of March, and that the antirachitic effect of April and May sunshine is about eight times that of December, January, and February. The same investigators also found that a considerable amount of ultra-violet irradiation takes place as a result of reflected rays from the sky and clouds, the antirachitic effect of which is approximately one-half to two-thirds of that produced by what is ordinarily termed sunshine—namely, direct rays from the sun plus reflected rays from the sky. All ultra-violet rays are not of value in preventing or curing rickets. In sunshine the most effective rays are the shortest, the wave-length of which ranges from 2900 to 3130 Angstrom units. Unfortunately, in those industrial areas of the British Isles where rickets is prevalent sunshine is somewhat rare, and any that may occur is almost valueless either for prevention or cure, since the smoke pall cuts off the ultra-violet rays. Moisture of the atmosphere, such a constant feature of our climate, also cuts off many of the rays. When the atmosphere is heavy with moisture, or polluted with smoke or dust, waves shorter than 3000, or even 3100, Angstrom units may be absorbed (Hess and Anderson).

Ordinary flint window glass completely cuts off all the curative ultra-violet rays, and, therefore, several substitutes for window glazing have been invented. The one best known in this country is Vita glass, which transmits rays down to 2900 Angstrom units. Tests on rachitic babies carried out in Boston, U.S.A., by exposing them to winter sunshine near windows, showed that Corning glass and quartz glass transmitted enough ultra-violet rays to cure rickets in very black babies, but whilst Vita glass transmitted light waves to the extreme limits of the sun rays, it did not transmit them in sufficient quantities to be of use in healing black babies during the winter months, but the observers thought that better results could be obtained if longer exposures to the sun rays were given. There are two differences between Boston and this country. In the first place, it is a city with very much less smoke than our industrial cities; and, secondly, the question of black pigmented babies is one of little importance here. Vita glass is unquestionably of value in country districts, but in my opinion it is practically useless in smoky cities.

Antirachitic powers can be conferred on certain foodstuffs by exposing them to the action of ultra-violet rays. Thus milk in both liquid and dried forms, wheat, and vegetables, such as spinach, carrots, &c., have been rendered antirachitic. On further investigation this property was found to be due to the activation of certain sterols, cholesterol in the animal, phytosterol in the vegetable compounds, and the administration of irradiated cholesterol and phytosterol was found to protect rats from rickets. Active cholesterol was also found to give a characteristic absorption spectrum in the ultra-violet region. The effect of administering irradiated cholesterol to children suffering from rickets was subsequently tried at the Children's Hospital, Birmingham, and we had the privilege of demonstrating the complete and rapid cure of a case of severe and resistant rickets. The details may be of some interest because the clinical experiment was controlled as carefully as possible.

The patient, aged 3 years, had received treatment by cod-liver oil from April to September, 1925—i.e., during the spring and summer months. He was admitted into hospital in September and for one month did not receive any antirachitic treatment, but was placed on the full hospital dietary. Radiograms taken 14 days after admission showed a slight degree of healing when compared with that taken on admission, possibly due to the effect of the cod-liver oil taken before admission, but no further healing of any moment occurred between the fourteenth and twenty-eighth days.

The child was then given 1 drachm three times a day of a 3 per cent. solution of irradiated cholesterol in linseed oil for a few days, and then the dose was increased to 2 drachms three times a day. In three weeks considerable healing had occurred, and complete healing was noted in 11 weeks.

The points to notice are: (1) that the case was one of a group of rickets which is somewhat resistant to cod-liver oil therapy; (2) that a period was allowed before starting cholesterol treatment, so that the effect of any delayed healing from cod-liver oil was eliminated; (3) that cure was produced in the autumn and winter months.

Later we used irradiated cholesterol in powder form in the treatment of cœliac disease, with and without rickets, with most encouraging results. The cholesterol used was chemically pure cholesterol and was irradiated by the method suggested by Hess.

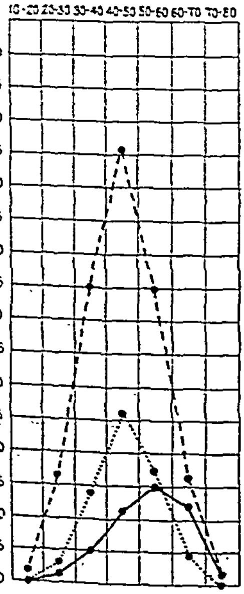
The antirachitic power of irradiated cholesterol diminishes after a time; also, unless certain precautions are taken, such as the removal of the ozone generated, prolonged irradiation renders cholesterol inactive again. We also found that some of the batches of irradiated cholesterol did not appear to be as potent as others. As a result of certain experiments, Heilbron, Kam, and Morton came to the conclusion that not cholesterol itself, but some substance associated with it is activated by irradiation, and Rosenheim and Webster found that chemically pure cholesterol, prepared by formation of its dibromo derivative and the reduction of this to cholesterol again, developed no antirachitic power after irradiation. These workers showed that only cholesterol obtained from natural sources—i.e., bile, brain, &c.—could be activated, but they came to the conclusion that the impurity itself must be a sterol since it formed an insoluble compound with digitonin. It was suggested by Windhaus that this sterol might be ergosterol, obtainable from ergot, yeast, &c., because it was the only known sterol having a structure likely to give it the required properties. Ergosterol was therefore investigated by them and also by Hess, and was found to develop intense antirachitic powers on irradiation, being about 2000 times as strong as ordinary cholesterol, and it, or a sterol closely similar to it, is now regarded as the impurity which is activated when natural cholesterol is irradiated. Ergosterol when irradiated is the most powerful antirachitic substance known; 1/10,000 mg. will protect rats from rickets, and it is estimated that 5 mg. are equivalent to 1 litre of the best cod-liver oil known. Irradiation leads to an obvious physical change in ergosterol, a yellowish resin being produced. How much of the substance is actually activated is not known, and it is possible that further experiments may yield more intensely antirachitic substances.

DIET AND VITAMINS.

In the clinical study of rickets two facts stand out. First, that the condition often develops in children who are fed on a diet rich in carbohydrates but poor in fat, such as condensed sweetened skimmed milk and many proprietary foods. Secondly, that in most instances it can be cured by the exhibition of cod-liver oil.

In 1918 Mellanby suggested that rickets might be due to the absence of an accessory food factor, and later stated that this antirachitic factor was probably identical with vitamin A. In his view cod-liver oil had the strongest, and vegetable oils scarcely any antirachitic action. Milk and yolk of egg contained a large amount of antirachitic substance. Mellanby's experiments and conclusions were, however, criticised adversely by many people. During the war Denmark exported large quantities of butter to Germany, with the result that poor people were unable to buy whole us to obtain definite figures of the end-results. It will thus be more valuable to consider whether we are satisfied with these results before discussing how we may more readily make an early diagnosis or improve the technical details of our treatment. When consulting the literature on this subject, there is found to be an extraordinary difference of opinion as to the value of surgical treatment. The early figures of Friedenwald[2] gave a most gloomy prognosis, for he found that of 1000 cases, only nine were capable of having a resection, and not one case was saved thereby. Cheever[1] also found that in a series of 236 cases, radical operation was only possible in 9·7 per cent. Many later figures give a much more hopeful outlook both as regards the possibility of performing a partial gastrectomy and of the ultimate end-results. Mayo[5] has estimated that a correct diagnosis should be made sufficiently early to permit at least 50 per cent. of radical operations, although in his own series the actual number in which a partial gastrectomy was possible was about 35 per cent. He also showed that out of 651 resections of the stomach, 38·6 per cent. were alive three years or more, and 26·5 per cent. were alive five years or more after operation. Paterson[6] also states that 24 per cent. of cases were alive and well three years after operation, and 15 per cent. after five years. Hayem[4] found that of 100 cases, 28 passed the three-year period without recurrence. I have given these observations at some length, for nine years' experience in a carefully controlled follow-up department has steadily strengthened my opinion that these later figures are much too optimistic, an opinion which I am not alone in holding. Gibson,[3] in a most valuable investigation in New York, states that "no sadder report of the disheartening status of cancer surgery has come to our attention." Of 70 cases of carcinoma of the stomach he found only one alive and well after five years, and also one only after three years. I regret to state that this experience is much more in accord with my own. It is true that we are all of us conversant with cases which have lived many years after operation. Hayem,[4] for instance, reports one who lived for 27 years, and Pearce Gould,[7] one who lived for 18 years and then had a recurrence. I also have seen a case operated upon by Mr. Hugh Lett in 1910, when I was his registrar, which was proved by microscopic examination, and who was readmitted in 1927 with an anæmia of the pernicious type which might or might not have been due to a recurrence. Such cases are, however, exceptional. In reviewing my own series the large proportion of inoperable cases is very startling. Of the 229 cases it was only possible to perform a partial gastrectomy in 78, that is, 33 per cent., a proportion probably smaller than is found with any other variety of carcinoma. It is, however, in the progress of these cases subjected to what is hoped to be a radical cure that so much disappointment lies. I have been making for the British Medical Association a careful analysis of the cases operated upon by myself in the years 1920–24 inclusive, and for the purpose of this present investigation I have added those cases operated upon before 1920. All the cases, therefore, have been operated upon for four or more years. They number in all 177, of which 62 were subjected to partial gastrectomy. Of these, three cannot be traced, one is well 15 years, one—the only sarcoma in the series—well 12 years, one well ten years, and one seven years after operation (see table).

FIG. 2.



Age-incidence of carcinoma and chronic ulceration.

Cases operated upon 1913–24		177
Partial gastrectomy		62
Not traced	3	
Died of recurrence	55	
Alive	4	
(15 years, 12 years, 10 years, 7 years = 1 each.)		
Total cases (1913–28)		229
Secondary to ulcer		25
Diagnosed as ulcer before operation		55

The remainder have all died with recurrences, some of which only appeared three or four years after operation, and although it is true that many patients have been given two or three years of happy life in place of the three to six months' misery, which would occur with no operation, yet these results must be regarded as being among the most depressing in surgery. In placing these figures before you, I at once lay myself open to the charge of having performed incomplete operations. It may be said, and it probably will be said, that such poor results could only be obtained by insufficient removal of the stomach or glands. It may only be my conceit that makes me believe that this is not the true explanation, but in many cases a very wide resection indeed has been carried out so that it would best be described as a subtotal gastrectomy, and I am very doubtful if a wider removal could have been effected. Moreover, in nearly all the cases recurrence has later taken place either in the liver or in the deep cœliac glands. Therefore I feel certain that improvement in the late results does not lie in more extensive operations, and also that the figures I have put before you give a more correct picture of the results obtained by surgical treatment than many that have been published.

Improved Diagnosis.

In attempting to better our results, it is at once evident that improvement is to be looked for along two lines. The fact that only one-third of the total number of cases are operable is evidence that correct diagnoses are not being made sufficiently early. A large number of my patients have been under medical treatment for prolonged periods, often in the belief that a simple ulcer was alone present, a point to which I shall have to return later. This is, however, only applicable to a certain number. One of the greatest difficulties with which we have to contend is that in not a few cases the symptoms are at first so slight and ill-defined that the patient either seeks no treatment, or attempts to improve his symptoms by the use of domestic remedies, only seeking skilled advice a few days before operation, at which time the disease is already hopelessly inoperable. It is, indeed, difficult to see how any improvement can be made with this class of case, for it is not feasible to suggest that apparently healthy people should, after the age of 40, have routine examinations which would have to include a test-meal and the use of X ray investigations. Some improvement may, however, be expected in this direction if doctors will remember and if the public can be made to realise that any persistent dyspepsia occurring after the age of 40 in a patient with a clear past history is to be regarded as due to carcinoma until this disease can be definitely eliminated.

Malignant Change in Gastric Ulcer.

It is, however, along the second line that the greatest improvement is to be expected. For many years Sir Berkeley Moynihan and others, including myself, have been laying stress upon the fact that a certain number of cases of gastric ulcer tend to least in Europe, since ancient times, although there is no reference to rickets in Hippocrates, Galen, or Celsus. Soranus of Ephesus, a physician who practised in Rome during the second century A.D., wrote thus :—

> The infant's feet become deformed from unwise attempts at walking. Frequent examples of such deformities are seen in Rome, due in most cases to ignorance and improper care of the infant. City women devote much less care to their infants than those in rural districts, hence the more frequent occurrence of these deformities among the infants of city dwellers.

☞ Surely Findlay is justified in regarding this as a description of rickets. We have, however, even more positive evidence that rickets existed 200 years before Glisson's time, for in the paintings of the *fifteenth century artists* of the Netherlands and Germany, especially those dealing with the Nativity, clinical evidence of rickets can be seen. In our own National Gallery there are several pictures of this type, but I will only mention one painted by the Netherlands artist, Dirk Bouts, in the year 1490. This picture shows definite evidence of rickets, not only in the child but also in the mother, whose forehead is an excellent example of Parrot's nodes. Anyone can multiply examples of this kind by exploring the galleries of Amsterdam, The Hague, &c. It is quite clear that in choosing models for such a subject the artist would not wittingly select those showing the stigmata of disease, but rather those approaching his ideal of perfect physical development. It is surely, therefore, a logical conclusion that in the fifteenth and sixteenth centuries, when the privations of war were frequently experienced by dwellers in the Low Countries, rickets was a common condition in the industrial cities of Holland and Germany (Foote).

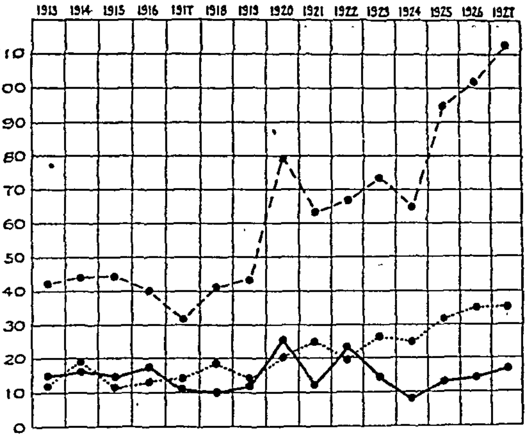
CARCINOMA OF STOMACH.*

By A. J. WALTON, M.S. LOND., F.R.C.S. ENG.,
SURGEON TO THE LONDON HOSPITAL.

IN the public mind there is a belief that cancer is not only uniformly fatal, but that it is rapidly increasing in frequency. Recent careful investigations have shown that this view is too pessimistic, and it has become quite evident that the different varieties of carcinoma vary considerably in their severity, many examples being permanently cured if subjected to early operative intervention. Of these varieties carcinoma of the stomach must, however, be considered one of the most unsatisfactory, for the early diagnosis is associated with much difficulty, and the late prognosis, as shown by more careful follow-up records, is not nearly so good as was at one time believed. It is therefore all the more satisfactory to note that there is little or no evidence that the disease is on the increase. Such a belief is based upon the returns of the Registrar-General, but these are probably of doubtful value, for with improvement in diagnostic methods cases are included that were previously omitted, and it is almost certain that many others are recorded as carcinoma when the diagnosis has not been confirmed by microscopic investigation. My own figures concern patients who have all been subjected to operation, and the diagnosis has therefore been proved either by visual inspection or by microscopical examination, confirmed in all cases by a careful observation of their after-progress. Thus, although small in number, they are of considerable interest. There has been *little or no* increase in the numbers operated upon year by year, whereas the proportion of cases of carcinoma to those of other lesions of the stomach has shown a very marked decrease. From 1913 to the present date the total number of cases of carcinoma of the stomach that have come to me for operation has been 229, and the total number of simple chronic ulcers 1086, the carcinomata thus forming about 17 per cent. of the total. In other words, of every six gastric operations one is performed for carcinoma of the stomach. The numbers of these lesions operated upon each year is shown in Fig. 1. This chart shows clearly that whereas the number of ulcer cases operated upon has multiplied nearly three times the number of carcinomata has remained nearly constant year by year.

Of more importance than the relationship to the total number of ulcers is that to ulcers of the body of the stomach, for it is this variety which is not only more likely to become carcinomatous, but is most commonly confused with carcinoma either before or during operation. Duodenal ulcers, on the other hand, may be said never to become carcinomatous, and it is this variety which has shown the greatest increase. Nevertheless, lesser curve ulcers are nearly three times as frequent in my present practice as they were in 1913.

FIG. 1.



Frequency of carcinoma and chronic ulceration. Total cases of carcinoma 229 (males 166, females 63); total cases of chronic ulcer 1086 (males 824, females 262).

In both figures the continuous line indicates "carcinoma," the interrupted line "all ulcers," and the dotted line "lesser curve ulcers."

It must be remembered that these figures, occurring as they do in the practice of one surgeon, are no evidence of an increase in the number of chronic ulcers in the general population, but since the ulcers have so greatly increased in number a corresponding increase would be expected in the numbers of carcinomata, and since it has not occurred it would suggest that carcinoma of the stomach is becoming a less frequent disease. The only explanation I can offer is that of recent years our work has been, as we should always wish it to be, preventive, and that many patients have been saved from carcinoma by having their ulcers treated surgically while they are yet benign.

The sex relationship of the two conditions shows that whereas both carcinomata and ulcers are much more common in the male, this frequency is more in evidence in the ulcers than in the carcinomata. Thus, of the 229 cases of carcinomata, 166 occurred in males and 63 in females; whereas of the 1086 ulcers, 824 were males and only 262 were females. There is also a distinct difference in the age-frequency. Carcinomata of the stomach is found most commonly between the ages of 40 and 70, the majority being present between 50 and 60; whereas the ulcers are more frequently detected earlier, being seen most commonly between the ages of 30 and 60, and with the greatest frequency between 40 and 50. In Fig. 2 the frequency of these lesions in the different decades is made apparent.

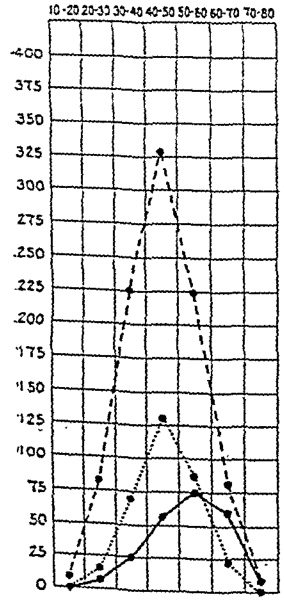
Results of Operation.

The operative treatment of carcinoma of the stomach has now been sufficiently long in vogue for us to obtain definite figures of the end-results. It will thus be more valuable to consider whether we are satisfied with these results before discussing how we may more readily make an early diagnosis or improve the technical details of our treatment. When consulting the literature on this subject, there is found to be an extraordinary difference of opinion as to the value of surgical treatment. The early figures of Friedenwald[2] gave a most gloomy prognosis, for he found that of 1000 cases, only nine were capable of having a resection, and not one case was saved thereby. Cheever[1] also found that in a series of 236 cases, radical operation was only possible in 9·7 per cent. Many later figures give a much more hopeful outlook both as regards the possibility of performing a partial gastrectomy and of the ultimate end-results. Mayo[5] has estimated that a correct diagnosis should be made sufficiently early to permit at least 50 per cent. of radical operations, although in his own series the actual number in which a partial gastrectomy was possible was about 35 per cent. He also showed that out of 651 resections of the stomach, 38·6 per cent. were alive three years or more, and 26·5 per cent. were alive five years or more after operation. Paterson[6] also states that 24 per cent. of cases were alive and well three years after operation, and 15 per cent. after five years. Hayem[4] found that of 100 cases, 28 passed the three-year period without recurrence. I have given these observations at some length, for nine years' experience in a carefully controlled follow-up department has steadily strengthened my opinion that these later figures are much too optimistic, an opinion which I am not alone in holding. Gibson,[3] in a most valuable investigation in New York, states that "no sadder report of the disheartening status of cancer surgery has come to our attention." Of 70 cases of carcinoma of the stomach he found only one alive and well after five years, and also one only after three years. I regret to state that this experience is much more in accord with my own. It is true that we are all of us conversant with cases which have lived many years after operation. Hayem,[4] for instance, reports one who lived for 27 years, and Pearce Gould,[7] one who lived for 18 years and then had a recurrence. I also have seen a case operated upon by Mr. Hugh Lett in 1910, when I was his registrar, which was proved by microscopic examination, and who was readmitted in 1927 with an anæmia of the pernicious type which might or might not have been due to a recurrence. Such cases are, however, exceptional. In reviewing my own series the large proportion of inoperable cases is very startling. Of the 229 cases it was only possible to perform a partial gastrectomy in 78, that is, 33 per cent., a proportion probably smaller than is found with any other variety of carcinoma. It is, however, in the progress of these cases subjected to what is hoped to be a radical cure that so much disappointment lies. I have been making for the British Medical Association a careful analysis of the cases operated upon by myself in the years 1920–24 inclusive, and for the purpose of this present investigation I have added those cases operated upon before 1920. All the cases, therefore, have been operated upon for four or more years. They number in all 177, of which 62 were subjected to partial gastrectomy. Of these, three cannot be traced, one is well 15 years, one—the only sarcoma in the series—well 12 years, one well ten years, and one seven years after operation (see table).

---

* Being a communication made to the International Cancer Conference, recently held in London.

FIG. 2.



Age-incidence of carcinoma and chronic ulceration.

Cases operated upon 1913–24		177
Partial gastrectomy		62
Not traced	3	
Died of recurrence	55	
Alive	4	
(15 years, 12 years, 10 years, 7 years = 1 each.)		
Total cases (1913–28)		229
Secondary to ulcer		25
Diagnosed as ulcer before operation		55

The remainder have all died with recurrences, some of which only appeared three or four years after operation, and although it is true that many patients have been given two or three years of happy life in place of the three to six months' misery, which would occur with no operation, yet these results must be regarded as being among the most depressing in surgery. In placing these figures before you, I at once lay myself open to the charge of having performed incomplete operations. It may be said, and it probably will be said, that such poor results could only be obtained by insufficient removal of the stomach or glands. It may only be my conceit that makes me believe that this is not the true explanation, but in many cases a very wide resection indeed has been carried out so that it would best be described as a subtotal gastrectomy, and I am very doubtful if a wider removal could have been effected. Moreover, in nearly all the cases recurrence has later taken place either in the liver or in the deep cœliac glands. Therefore I feel certain that improvement in the late results does not lie in more extensive operations, and also that the figures I have put before you give a more correct picture of the results obtained by surgical treatment than many that have been published.

Improved Diagnosis.

In attempting to better our results, it is at once evident that improvement is to be looked for along two lines. The fact that only one-third of the total number of cases are operable is evidence that correct diagnoses are not being made sufficiently early. A large number of my patients have been under medical treatment for prolonged periods, often in the belief that a simple ulcer was alone present, a point to which I shall have to return later. This is, however, only applicable to a certain number. One of the greatest difficulties with which we have to contend is that in not a few cases the symptoms are at first so slight and ill-defined that the patient either seeks no treatment, or attempts to improve his symptoms by the use of domestic remedies, only seeking skilled advice a few days before operation, at which time the disease is already hopelessly inoperable. It is, indeed, difficult to see how any improvement can be made with this class of case, for it is not feasible to suggest that apparently healthy people should, after the age of 40, have routine examinations which would have to include a test-meal and the use of X ray investigations. Some improvement may, however, be expected in this direction if doctors will remember and if the public can be made to realise that any persistent dyspepsia occurring after the age of 40 in a patient with a clear past history is to be regarded as due to carcinoma until this disease can be definitely eliminated.

Malignant Change in Gastric Ulcer.

It is, however, along the second line that the greatest improvement is to be expected. For many years Sir Berkeley Moynihan and others, including myself, have been laying stress upon the fact that a certain number of cases of gastric ulcer tend to least in Europe, since ancient times, although there is no reference to rickets in Hippocrates, Galen, or Celsus. Soranus of Ephesus, a physician who practised in Rome during the second century A.D., wrote thus :—

> The infant's feet become deformed from unwise attempts at walking. Frequent examples of such deformities are seen in Rome, due in most cases to ignorance and improper care of the infant. City women devote much less care to their infants than those in rural districts, hence the more frequent occurrence of these deformities among the infants of city dwellers.

Surely Findlay is justified in regarding this as a description of rickets. We have, however, even more positive evidence that rickets existed 200 years before Glisson's time, for in the paintings of the fifteenth century artists of the Netherlands and Germany, especially those dealing with the Nativity, clinical evidence of rickets can be seen. In our own National Gallery there are several pictures of this type, but I will only mention one painted by the Netherlands artist, Dirk Bouts, in the year 1490. This picture shows definite evidence of rickets, not only in the child but also in the mother, whose forehead is an excellent example of Parrot's nodes. Anyone can multiply examples of this kind by exploring the galleries of Amsterdam, The Hague, &c. It is quite clear that in choosing models for such a subject the artist would not wittingly select those showing the stigmata of disease, but rather those approaching his ideal of perfect physical development. It is surely, therefore, a logical conclusion that in the fifteenth and sixteenth centuries, when the privations of war were frequently experienced by dwellers in the Low Countries, rickets was a common condition in the industrial cities of Holland and Germany (Foote).

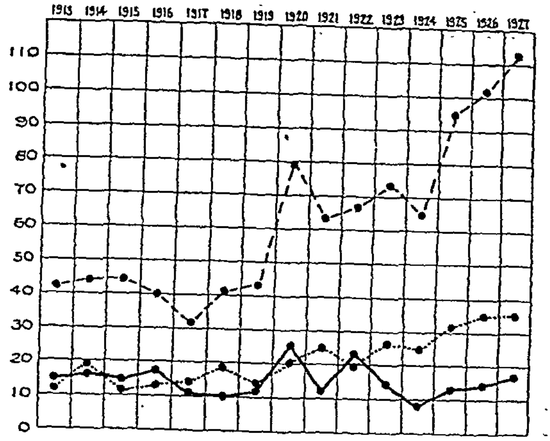
CARCINOMA OF STOMACH.*

BY A. J. WALTON, M.S. LOND., F.R.C.S. ENG.,
SURGEON TO THE LONDON HOSPITAL.

IN the public mind there is a belief that cancer is not only uniformly fatal, but that it is rapidly increasing in frequency. Recent careful investigations have shown that this view is too pessimistic, and it has become quite evident that the different varieties of carcinoma vary considerably in their severity, many examples being permanently cured if subjected to early operative intervention. Of these varieties carcinoma of the stomach must, however, be considered one of the most unsatisfactory, for the early diagnosis is associated with much difficulty, and the late prognosis, as shown by more careful follow-up records, is not nearly so good as was at one time believed. It is therefore all the more satisfactory to note that there is little or no evidence that the disease is on the increase. Such a belief is based upon the returns of the Registrar-General, but these are probably of doubtful value, for with improvement in diagnostic methods cases are included that were previously omitted, and it is almost certain that many others are recorded as carcinoma when the diagnosis has not been confirmed by microscopic investigation. My own figures concern patients who have all been subjected to operation, and the diagnosis has therefore been proved either by visual inspection or by microscopical examination, confirmed in all cases by a careful observation of their after-progress. Thus, although small in number, they are of considerable interest. There has been little or no increase in the numbers operated upon year by year, whereas the proportion of cases of carcinoma to those of other lesions of the stomach has shown a very marked decrease. From 1913 to the present date the total number of cases of carcinoma of the stomach that have come to me for operation has been 229, and the total number of simple chronic ulcers 1086, the carcinomata thus forming about 17 per cent. of the total. In other words, of every six gastric operations one is performed for carcinoma of the stomach. The numbers of these lesions operated upon each year is shown in Fig. 1. This chart shows clearly that whereas the number of ulcer cases operated upon has multiplied nearly three times the number of carcinomata has remained nearly constant year by year.

Of more importance than the relationship to the total number of ulcers is that to ulcers of the body of the stomach, for it is this variety which is not only more likely to become carcinomatous, but is most commonly confused with carcinoma either before or during operation. Duodenal ulcers, on the other hand, may be said never to become carcinomatous, and it is this variety which has shown the greatest increase. Nevertheless, lesser curve ulcers are nearly three times as frequent in my present practice as they were in 1913.

FIG. 1.



Frequency of carcinoma and chronic ulceration. Total cases of carcinoma 229 (males 166, females 63); total cases of chronic ulcer 1086 (males 824, females 262).

In both figures the continuous line indicates "carcinoma," the interrupted line "all ulcers," and the dotted line "lesser curve ulcers."

It must be remembered that these figures, occurring as they do in the practice of one surgeon, are no evidence of an increase in the number of chronic ulcers in the general population, but since the ulcers have so greatly increased in number a corresponding increase would be expected in the numbers of carcinomata, and since it has not occurred it would suggest that carcinoma of the stomach is becoming a less frequent disease. The only explanation I can offer is that of recent years our work has been, as we should always wish it to be, preventive, and that many patients have been saved from carcinoma by having their ulcers treated surgically while they are yet benign.

The sex relationship of the two conditions shows that whereas both carcinomata and ulcers are much more common in the male, this frequency is more in evidence in the ulcers than in the carcinomata. Thus, of the 229 cases of carcinomata, 166 occurred in males and 63 in females; whereas of the 1086 ulcers, 824 were males and only 262 were females. There is also a distinct difference in the age-frequency. Carcinomata of the stomach is found most commonly between the ages of 40 and 70, the majority being present between 50 and 60; whereas the ulcers are more frequently detected earlier, being seen most commonly between the ages of 30 and 60, and with the greatest frequency between 40 and 50. In Fig. 2 the frequency of these lesions in the different decades is made apparent.

Results of Operation.

The operative treatment of carcinoma of the stomach has now been sufficiently long in vogue for second and third year, five between the third and fourth year, and two after four years. My chief reason for putting these figures before you, however, is to impress upon you my belief that in this, as in other branches of medicine, the greatest progress has been and is still to be made by the use of preventive measures. An understanding of the cause of carcinoma implying, as I believe it does, a knowledge as to why a cell reverts from its unipotential character to a totipotential phase, still seems far from us, and until that time arrives, the greatest hope of preventing carcinoma of the stomach lies in the free surgical removal of all chronic ulcers. If the lay press, altering their present views, will help us with the great weight of their authority to teach the public that the majority of such ulcers should be excised, much will be accomplished in diminishing the frequency of this dread disease.

SYPHILIS OF THE ŒSOPHAGUS.

WITH A REPORT OF TWO CASES.

BY A. LAWRENCE ABEL, M.S. LOND., F.R.C.S. ENG.,
SURGEON TO THE KENSINGTON GENERAL AND LONDON LOCK HOSPITALS; ASSISTANT SURGEON TO THE WOOLWICH WAR MEMORIAL HOSPITAL, ETC.

SYPHILIS of the œsophagus is only diagnosed in one or two of every 1000 cases presenting themselves with an œsophageal lesion. It occurs, however, in all cases of acute syphilis which remain untreated until the so-called "secondary" stage is established, but only as a part of the general inflammation of all mucous membranes, and usually there is a complete absence of any œsophageal syndrome. It is not until a secondary œsophagitis is present, or a spasmodic or organic stenosis appears, that cases of syphilis of the œsophagus come to the hands of the œsophagoscopist for diagnosis and treatment. I shall confine these remarks, therefore, to a description of syphilis of the œsophagus accompanied by the cardinal symptom of dysphagia.

Pathology.

Syphilis of the œsophagus occurs rarely in the congenital form of the disease. More commonly, in the so-called "secondary" stage, it may give rise to an œsophagitis, of such severity as to be manifested by dysphagia. The condition rapidly responds to appropriate treatment, and is very seldom followed by stenosis.

During the so-called "tertiary" period syphilis of the œsophagus is still more common, and takes the form of localised gummata. The gumma usually arises in either the upper or lower third of the canal, and on rupture produces a typical gummatous ulcer with a clearly cut edge and an unhealthy yellow base. There is considerable local induration, which, together with the concomitant spasm, is the main cause of the obstruction to the lumen. Leukoplakic patches may occur in the neighbourhood; some local non-specific œsophagitis may be present, together with a little hypertrophy of the wall and dilatation of the œsophagus above the level of the lesion.

Diagnosis.

The symptoms are those of painless dysphagia, together with those of any other syphilitic lesion which may coexist. If, however, there is any pharyngeal lesion, painful dysphagia occurs, together with some local spasm and regurgitation.
